(5.) *Cones of Tuff and Lava*—These are by far the most frequent. They may be taken, indeed, as the typical form of volcanoes. Around the central vent the successive showers of scorie and a-hes gather, with occasional streams of lava, which from time to time descend different sides of the growing cone. The component strata have thus the usual inclination outwards, though, when seen in section along the crater-walls, they look approximately horizontal. By continued explosious fissures are formed in the sides of the cone. These are injected with lava, producing a network of dykes which strengthen the cone, or they serve as channels of escape for lava, and give rise to lateral eruptions and minor or parasitic cones. As the main cone increases in diameter by the accumulation of fragmentary and molten ejections, it rises also in height, until at last few or no eruptions take place from its summit, but only from openings on its flanks.

(6.) *Submarine Volcanoes*.—It is not only on the surface of the land that volcanic action shows itself. It takes place likewise under the sea, and as the geological records of the earth's past history are chiefly marine formations, the characteristics of submarine volcanic action have no small interest to the geologist. Unfortunately, the phenomena of recent volcanic eruptions under the sea are for the most part inaccessible. Here and there, as among the islands of the Greek Archipelago and at Tahiti, elevation of the seabed has taken place, and brought to the surface beds of lava, which had been erupted and had consolidated under water. There does not appear to be any appreciable difference either in external aspect or in internal structure between such submarine lavas and those erupted on the land. Some of them are highly scoriaceous. There is no reason indeed why slaggy lava and loose scorie should not accumulate under the pressure of a deep column of the ocean. At the Hawaii Islands, on 25th February 1877, masses of pumice, during a submarine volcanic explosion, were ejected to the surface, one of which struck the bottom of a boat with considerable violence and then floated. At the same time, when we reflect to what a considerable extent the bottom of the great ocean basins is dotted over with volcanic cones, rising often solitary from profound depths, we can understand how large a proportion of the actual eruptions may take place under the sea. The foundations of these volcanic islands doubtless consist of submarine lavas and fragmentary materials, which, in each case, continued to accumulate to a height of two or three miles, until the pile reached the surface of the water and the phenomena became subaerial. The immense abundance and wide diffusion of volcanic detritus over the bottom of the Pacific and Atlantic Oceans, even at distances remote from land, as has been made known by the voyage of the "Challenger," may indicate the prevalence and persistence of submarine volcanic action, though, at the same time, it must be admitted that an extensive diffusion of volcanic debris from the islands is effected by winds and ocean-currents.

4. Geographical Distribution of Volcanoes.

The chief facts under this head may thus be summarized. (1.) Volcanoes occur along the margins of the ocean basins, particularly along lines of dominant mountain ranges. The vast hollow of the Pacific is girdled with a wide ring of volcanic foci. (2.) They rise as a striking feature in the heart of the ocean basins. Most of the oceanic islands are volcanic. Even the coral islands have in all likelihood been built upon the tops of submarine volcanic cones. (3.) Volcanoes are thus situated, as a rule, close to the sea. When they occur inland they sometimes appear in the neighbourhood of a large sheet of water. Yet so many instances have been observed where volcanoes have appeared at great distances from any sheet of water that the proximity of a lake or of

the sea cannot be regarded as necessary for the evolution of volcanic phenomena. (4.) The dominant arrangement of volcanoes is in lines along subterranean lines of weakness, as in the chain of the Andes, the Aleutian Islands, and the Malay Archipelago. (5.) Where the linear arrangement does not hold, it gives place to one in groups, as in Italy, Iceland, and the volcanic islands of the great oceans.

§ 5. Distribution of Volcanic Action in Time.

Besides the existence of what are called extinct volcanoes, the geologist can adduce proofs of the former presence of active volcanoes in many countries where cones and craters and all ordinary aspects of volcanic mountains have long disappeared. Sheets of lava, beds of tuff, dykes, and necks representing the sites of volcanic vents have been recognized abundantly. These manifestations of volcanic action, moreover, have as wide a range in geological time as they have in geographical area. Every great geological period, back at least as far as the Lower Silurian, has had its volcanoes. In Britain, for instance, there were active volcanic vents in the Lower Silurian period, whence the lavas and tufts of Snowdon, Aran Mowdwy, and Cader Idris were ejected. The Lower Old Red Sandstone epoch was one of prolonged volcanic activity in central Scotland. The earlier half of the Carboniferous period likewise witnessed the outburst of innumerable small volcanoes over the same region. During the Permian period a few scattered vents existed in the south-west of Scotland, and in the time of the New Red Sandstone some similar points of eruption appeared in the south of England. The older Tertiary ages were distinguished by the outpouring of the enormous basaltic plateaus of Antrim and the Inner Hebrides.

Thus it can be shown that, within the same comparatively limited geographical space, volcanic action has been rife at intervals during a long succession of geological ages. The existing active volcanoes of Iceland rise from amid Tertiary lavas and tufts, which form part of a great volcanic ridge, extending down through the Faroe Islands into the west of Britain. Volcanic action, which now manifests itself so conspicuously along certain lines, seems to have continued in that linear development for protracted periods of time. The actual vents have changed, dying in one place and breaking out in another, yet keeping on the whole along the same lines.

§ 6. Causes of Volcanic Action.

Volcanoes depend, of course, upon the internal heat of the planet as their prime source of energy. But the *modus operandi* whereby that internal heat manifests itself in volcanic action is a problem by no means of easy solution. Were this action merely an expression of the intensity of the heat, we might expect it to have manifested itself in a far more powerful manner in former periods, and to exhibit a regularity and continuity commensurate with the exceedingly slow diminution of the earth's temperature. But there is no geological evidence in favour of greater volcanic intensity in ancient times than in more recent periods; on the contrary, it may be doubted whether any of the Palaeozoic volcanoes equalled in magnitude those of the Tertiary period, or whether any of the latter ever produced such stupendous changes as have been effected by modern volcanoes still active. On the other hand, no feature of volcanic action is more conspicuous than its spasmodic fitfulness.

The mere presence of a high internal temperature, therefore, would probably not of itself produce the phenomena of volcanoes, at least in the present condition of the planet. There can be no doubt that one essential exciting cause of volcanic action is the descent of water from the surface. It has already been pointed out how invariably steam plays

a chief part in volcanic eruptions, how it issues in vast clouds from the crater, and continues to rise copiously from the lava even after the molten rock has travelled for some miles, and has assumed a solid surface. The quantity of water which descends into the interior must be enormous. The floor of the sea, the beds of rivers and lakes, are all leaky. Of the annual rain which sinks beneath the surface of the land, we cannot tell what proportion is detained and prevented from rising again in springs. Not only does this subterranean water percolate down cracks and joints, it infiltrates through the very pores of the rocks, and can do so even against the pressure of steam on the further side.

Accordingly, there has arisen a very prevalent belief among geologists, that it is to the enormous expansive force of perhaps white-hot water finding access to, and imprisoned in, some of the heated empty spaces at the roots of volcanoes that the explosions of a crater and the subsequent rise of a lava-column are due. It has been supposed that, somewhat like the reservoirs in which the hot water and steam accumulate under the Icelandic geysers, these volcanic spaces receive a constant influx of water from the surface, which cannot escape by other channels, but is in great part converted into vapour or retained in the fluid state at an enormously high temperature and under vast pressure. In the course of time, the materials filling up the chimney are unable to withstand the upward expansion of this impounded vapour and water, so that, after some premonitory rumblings, the whole opposing mass is blown out, and the vapour rushes up in the well-known masses of cloud. Meanwhile, the removal of the overlying column relieves some of the pressure from the water-charged lava, which therefore begins to rise in the funnel until it forces its way through some weak part of the cone, or pours over the top of the crater. After a time the vapour is expended, the energy of the volcano ceases, and there comes a variable period of repose, until a renewal of the same phenomena brings on another eruption. By such successive paroxysms it is supposed that the foam of the internal reservoirs and tunnels become changed, new spaces for the accumulation of superheated water are formed, whence in time new volcanic vents issue, while the old ones gradually die out.

As physical considerations negative the idea of a comparatively thin crust surmounting a molten interior whence volcanic energy might be derived, geologists have found themselves involved in great perplexity to explain volcanic phenomena for the production of which a source of no great depth would seem to be necessary. They have supposed the existence of pools or lakes of liquid lava lying beneath the crust, and at an inconsiderable depth from the surface. They have sometimes appealed to the influence of the contraction of the earth's mass, assuming that the contraction is greater in the outer than in the inner portions, and that the effect of this must be to squeeze out some of the internal molten matter through weak parts of the crust. Cordier, for example, calculated that a contraction of only a single millimetre (about $\frac{1}{25}$ th of an inch) would suffice to force out to the surface lava enough for 500 eruptions, allowing 1 cubic kilometre (about 1300 million cubic yards) for each eruption.

The influence of contraction as the grand source of volcanic energy has recently been insisted upon on quite different grounds by Mr Mallet, who has developed the theory that all the present manifestations of hypogean action are due directly to the more rapid contraction of the hotter internal mass of the earth, and the consequent crushing in of the outer cooler shell. He points to the admitted difficulties in the way of connecting volcanic phenomena with the existence of internal lakes of liquid matter, or of a central ocean of molten rock. Observations made by him, on the effects of the earthquake shocks accompanying the

volcanic eruptions of Vesuvius and of Etna, showed that the focus of disturbance could not be more than a few miles deep,—that, in relation to the general mass of the globe, it was quite superficial, and could not possibly have lain under a crust of 800 miles or upwards in thickness. The occurrence of volcanoes in lines, and especially along some of the great mountain-chains of the planet, is likewise dwelt upon by him as a fact not satisfactorily explicable on any previous hypothesis of volcanic energy. But he contends that all these difficulties disappear when once the simple idea of cooling and contraction is adequately realized. "The secular cooling of the globe," he remarks, "is always going on, though in a very slowly descending ratio. Contraction is therefore constantly providing a store of energy to be expended in crushing parts of the crust, and through that providing for the volcanic heat. But the crushing itself does not take place with uniformity, it necessarily acts *per saltum* after accumulated pressure has reached the necessary amount at a given point, where some of the pressed mass, unequally pressed as we must assume it, gives way, and is succeeded perhaps by a time of repose, or by the transfer of the crushing action elsewhere to some weaker point. Hence, though the magazine of volcanic energy is being constantly and steadily replenished by secular cooling, the effects are intermittent." He offers an experimental proof of the sufficiency of the store of heat produced by this internal crushing to cause all the phenomena of existing volcanoes. The slight comparative depth of the volcanic foci, their linear arrangement, and their occurrence along lines of dominant elevation become, he contends, intelligible under this hypothesis. For, since the crushing in of the crust may occur at any depth, the volcanic sources may vary in depth indefinitely, and as the crushing will take place chiefly along lines of weakness in the crust, it is precisely in such lines that crumpled mountain-ridges and volcanic funnels should appear. Moreover, by this explanation it is sought to harmonize the discordant observations regarding the variations in the rate of increase of temperature downward within the earth. In some parts of the crust the crushing must be much greater than in other parts, and since the heat "is directly proportionate to the local tangential pressure which produces the crushing and the resistance thereto," it may vary indefinitely up to actual fusion. So long as the crushed rock remains out of reach of a sufficient access of subterranean water, there would, of course, be no disturbance. But if, through the weaker parts, water enough should descend and be absorbed by the intensely hot crushed mass, it would be raised to a very high temperature, and, on sufficient diminution of pressure, would flash into steam and produce the commotion of a volcanic eruption.

This ingenious theory requires the operation of sudden and violent movements, or at least that the heat generated by the crushing should be more than can be immediately conducted away through the crust. Were the crushing slow and equable, the heat developed by it would doubtless be tranquilly dissipated through the crust, the temperature of which might not be sensibly affected in the process, or not to such an extent as to cause any appreciable molecular rearrangement of the particles of the rock. Moreover, as the action is general throughout the whole mass of the outer shell, there does not seem in the theory any valid reason why volcanic action should be limited to particular lines, and why it should continue so long persistently on these lines. The existence of weak parts of the crust is postulated, but the successive crushings and consequent fusions might be expected to strengthen these weaker parts and to make volcanic conditions less easy.

It cannot indeed be denied that there exists the most

convincing geological evidence in favour of the secular contraction of the globe, that during the process masses of sedimentary strata, many thousands of feet in thickness, have been crumpled and crushed, and that the crumpling has often been accompanied by such an amount of heat and evolution of chemical activity as to produce a movement and rearrangement of the elements of the rocks,—thus change sometimes advancing to the point of actual fusion. There is reason to believe that some at least of these periods of intense terrestrial disturbance have been followed by periods of prolonged volcanic action in the disturbed areas. Mr. Mallet's theory is thus, to some extent, supported by independent geological testimony. The existence, however, of large reservoirs of fused rock, at a comparatively small depth beneath the surface, may be conceived as probable, apart altogether from the effects of the subsidence of the outer shell upon the inner nucleus. The connexion of volcanoes with lines of elevation, and consequent weakness in the earth's crust, is precisely what might have been anticipated on the view that the nucleus, though practically solid, is at such a temperature and pressure that any diminution of the pressure, by corrugation of the crust or otherwise, will cause the subjacent portion of the nucleus to melt. It is along the lines of elevation that the pressure must be relieved, and it is there that the consequent melting will take place. On these lines of tension and weakness, therefore, the conditions for volcanic excitement must be best developed. Water is there able soonest to reach the intensely-heated materials underneath the crust, and to give rise to the volcanic explosions. The periodicity of eruptions will thus depend upon the length of time required for the storing up of sufficient steam, and on the amount of resistance in the crust to be overcome. In some cases the intervals of activity, like those of the geysers, return with considerable regularity. In other cases, the shattering of the crust, or the upwelling of vast masses of lava, or the closing of subterranean passages for the descending water, or other causes may vary the conditions so much, from time to time, that the eruptions may follow each other at very unequal periods, and with very discrepant energy. Each great outburst exhausts for a while the vigour of the volcano, and an interval is needed for the renewed accumulation of vapour.

Section II.—Earthquakes.

The phenomena of earthquake-motion having been discussed in the article EARTHQUAKES, we shall notice here only those which have a marked geological importance from the way in which they affect the crust or surface of the earth, briefly describing the effects of earthquakes upon the surface of the land, and upon terrestrial and oceanic waters, the permanent changes of level occasioned by them, their distribution and geological relations, and their causes.

1. *Effects upon the Soil and General Surface of a Country.*—The earth-wave or wave of shock underneath a country may traverse a wide region and affect it violently at the time without leaving any trace of its passage. Loose objects, however, are apt to be displaced. Thus blocks of rock, already disengaged from their parent masses, may be rolled down into the valleys below. Large landslips are thus produced, and these may give rise to very considerable subsequent changes in the drainage of the localities where they take place. It has often been observed that the soil is rent by the passage of the earthquake. Fissures appear, varying in size from mere cracks, like those due to desiccation, up to deep and wide chasms. Where these cracks are numerous, and where, consequently, the ground has been much disturbed, permanent modifications of the landscape may be produced. Trees are thrown down and buried, wholly or in part, in the rents. These superficial

effects may, in a few years, be effaced by the gradual levelling power of the atmosphere. Where, however, the chasms are wide and deep enough to intercept any rivulets, or to serve as channels for heavy rain-flooding, they are sometimes further excavated, so as to become gradually enlarged into ravines and valleys. As a rule, each rent is only a few yards long. Sometimes it may extend for half a mile or even more. In the earthquake which shook the South Island of New Zealand in 1848, a fissure was formed averaging 18 inches in width and traceable for a distance of 60 miles parallel to the adjacent axis of the mountain-chain. The subsequent earthquake of 1855, in the same region, gave rise to a fracture which could be traced along the base of a line of cliff for a distance of about 90 miles.

Remarkable circular cavities are sometimes formed in the ground during the passage of the earth-wave. In many cases these holes serve as funnels of escape for an abundant discharge of water, so that when the disturbance ceases they appear as pools. They are believed to be caused by the sudden collapse of subterranean water-channels and the consequent forcible ejection of the water to the surface.

2. *Effects upon Terrestrial Waters.*—Springs are temporarily affected by earthquake movements, becoming greater or smaller in volume, sometimes muddy or discoloured, and sometimes increasing in temperature. Brooks and rivers have been observed to flow with an interrupted course, increasing or diminishing in size, stopping in their flow so as to leave their channels dry, and rolling forward with increased rapidity. Lakes are still more sensitive to the tremors of the ground beneath. Their waters occasionally rise and fall for several hours, even at a distance of many hundred miles from the centre of disturbance. Thus, on the day of the great Lisbon earthquake, many of the lakes of central and north-western Europe were so affected as to maintain a succession of waves rising to a height of 2 or 3 feet above their usual level. Cases, however, have been observed where, owing to excessive subterranean movement, lakes have been emptied of their contents and their beds left permanently dry. On the other hand, areas of dry ground have been depressed, and have become the sites of new lakes.

Some of the most important changes in the fresh water of a region, however, are produced by the fall of masses of rock and earth. Landslips, by damming up a stream, may so arrest its water as to form a lake. The barrier, if of sufficient strength, may be permanent, and the lake will then remain. Owing, however, to the usually loose, incoherent character of its materials, the dam thrown across the pathway of a stream runs a great risk of being undermined by the percolating water. When this is the case, a sudden giving way of the barrier will allow the confined water to rush with great violence down the valley, and produce perhaps tenfold more havoc there than may have been caused by the original earthquake. When the landslip is of sufficient dimensions to divert the stream from its previous course, the new channel thus taken may become permanent, and a valley may be cut out or widened.

3. *Effects upon the Sea.*—The great sea-wave propagated outward from the centre of a sub-oceanic earthquake, and reaching the land after the earth-wave has arrived there, gives rise to much destruction along the maritime parts of the disturbed region. As it approaches the shore, the littoral waters retreat seawards, sucked up, as it were, by the advancing wall of water, which, reaching a height of some times 60 feet, rushes over the bare beach and sweeps inland, carrying with it everything which it can dislodge and bear away. Loose blocks of rock are thus lifted to a considerable distance from their former position, and left at a higher level. Deposits of sand, gravel, and other superficial

accumulations are torn up and swept away, while the surface of the country, as far as the limit reached by the wave, is strewn with debris. If the district has been already shattered by the passage of the earth-wave, the advent of the great sea-wave augments and completes the devastation.

4. *Permanent Changes of Level.*—It has been observed, after the passage of an earthquake, that the level of the disturbed country has been changed. Thus after the terrible earthquake of 19th November 1822 the coast of Chili for a long distance was found to have risen from 3 to 4 feet, so that along the shore the littoral shells were exposed adhering still to the rocks amid multitudes of dead fish. The same coast-line has since been further upraised by subsequent earthquake shocks. On the other hand, many instances have been observed where the effect of the earthquake has been to depress permanently the disturbed ground. For example, by the Bengal earthquake of 1762 an area of 60 square miles on the coast, near Chittagong, suddenly went down beneath the sea, leaving only the top of the higher eminences above water. The succession of earthquakes which in the years 1811 and 1812 devastated the basin of the Mississippi gave rise to widespread depressions of the ground, over some of which the river spread so as to form new lakes, with the tops of the trees still standing above the surface of the water.

5. *Distribution and Geological Relations of Earthquakes.*—While no large space of the earth's surface seems to be free from at least some degree of earthquake-movement, there are regions more especially liable to the visitation. As a rule, earthquakes are most frequent in volcanic districts, the explosions of a volcano being very generally preceded or accompanied by tremors of greater or less intensity. In the Old World the great belt of earthquake disturbance stretches in an east and west direction, along that tract of remarkable depressions and elevations lying between the Alps and the mountains of northern Africa, and spreading eastward so as to enclose the basins of the Mediterranean, Black Sea, Caspian, and Sea of Aral, and to rise into the great mountain-ridges of Central Asia. In this zone lie numerous volcanic vents, both active and extinct or dormant, from the Azores on the west to the basaltic plateaus of India on the east. The Pacific Ocean is surrounded with a vast ring of volcanic vents, and its borders are likewise subject to frequent earthquake shocks. Some of the most terrible earthquakes within human experience have been those which have affected the western seaboard of South America.

6. *Causes of Earthquakes.*—An earthquake shock has been defined by Mr Mallet as the transit of a wave of elastic compression through the crust and surface of the earth, generated by some sudden impulse within the crust. The passage of such a wave has been imitated experimentally, and some of its characteristic features have been illustrated by accidental explosions at powder-works. But though the phenomena point to some sudden and violent blow inflicted upon the solid crust, it is impossible to do more than speculate on the probable nature of this blow. In some cases it may arise from the sudden flashing into steam of water in the spheroidal state, from the sudden condensation of steam, from the explosions of a volcanic orifice, from the falling in of the roof of a subterranean cavity, or from the sudden snap of subterranean rocks subjected to prolonged and intense strain. But we are still in ignorance as to the actual immediate cause of any earthquake in regions remote from active volcanoes. So much, at least, is certain, that the shock must arise from some sudden and violent impulse, whereby a wave or undulation is propagated in all directions through the solid substance of the crust.

Section III.—Secular Upheaval and Depression.

Besides the sudden movements due to earthquake-shocks, the crust of the earth undergoes in many places oscillations of an extremely quiet and uniform character, sometimes of an elevatory, sometimes of a subsiding nature. So tranquil are these changes that they produce from day to day no appreciable alteration in the aspect of the ground affected. Only after the lapse of several generations, and by means of careful measurements, can they really be proved. Indeed, in the interior of a country nothing but a series of accurate levellings from some unchanged datum-line might detect the change of level, unless the effects of this terrestrial movement showed themselves in altering the drainage. It is only along the sea-coast that a ready measure is afforded of any such movement. In popular language it is usual to speak of the sea as rising or sinking relatively to the land. But so long as the volume of the ocean remains the same, the general sea-level can neither rise nor fall, unless by some movement of the solid globe underneath it. And, as we cannot conceive of any possible augmentation of the oceanic waters, nor of any diminution save what may be due to the extremely slow process of abstraction by the hydration of minerals, or absorption into the earth's interior, we are compelled to regard the sea-level as practically a constant datum-line, any deviation from which, in the apparent heights of sea and land, must be due to movement of the land and not of the sea.

There are indeed certain cosmical causes which may affect the relative levels of sea and land. Thus the accumulation of large masses of snow and ice as an ice-cap at one of the poles would, as has been before pointed out (*ante*, p. 217), tend to displace the earth's centre of gravity, and as a consequence to raise the level of the ocean in the hemisphere so affected, and to diminish it in a corresponding measure elsewhere. The return of the ice into the state of water would produce an opposite effect. Dr Croll has also drawn attention to the fact that, as a consequence of the diminution of centrifugal force owing to the retardation of the earth's rotation caused by the tidal wave, the sea-level must have a tendency to subside at the equator and rise at the poles. A larger amount of land need not ultimately be laid bare at the equator, for the change of level resulting from this cause would be so slow that the general degradation of the surface of the land might keep pace with it, and diminish the terrestrial area as much as the retreat of the ocean tended to increase it. Dr Croll has further pointed out that the waste of the equatorial land, and the deposition of the detritus in higher latitudes, must still further counteract the effects of retardation and the consequent change of ocean-level.¹

Such widespread general causes of change must produce equally far-reaching effects. But in examining the changes of level between land and sea, we find them to be eminently local and variable in character, pointing to some local and unequally acting cause,—so that, while admitting these cosmical and widespread influences to be part of the general system of geological change, we must yet hold the sea-level, for all practical purposes, to be invariable, any apparent oscillations of that level upon the land being due to terrestrial movements.

§ 1. *Movements of Upheaval.*

Various maritime tracts of the land have been ascertained to have undergone in recent times, or to be still undergoing, a gradual elevation above the sea. Thus, the coast of Siberia, for 600 miles to the east of the river Lena, the western tracts of South America, and the Scandinavian peninsula, with the exception of a small area at its southern

¹ Croll, *Phil. Mag.*, 1868, p. 382; Sir W. Thomson, *Trans. Geol. Soc. Glasgow*, iii. 223.

apex, have been proved to have been recently upheaved. The proofs of this change of level chiefly to be relied on are the following¹ —

(1.) The position of rocks covered with barnacles or other littoral adherent animals, or pierced by lithodromous shells. A single stone with these creatures on its surface would not necessarily prove anything, for it might be cast up by a storm, but a line of large boulders, which had evidently not been moved since the crinoides and molluscs lived upon them, and still more a solid cliff with these marks of littoral or sub-littoral life upon its base, now raised above high-water mark, would be sufficient to demonstrate a rise of land. The amount of the upheaval might be pretty accurately determined by measuring the vertical distance between the upper edge of the barnacle zone upon the upraised rock, and the limit of the same zone on the present shore.

(2.) A line of sea-caves, now standing at a distance above high water-mark beyond the reach of the sea, would afford evidence of recent uprise, since caves of this kind are only hollowed out by the waves between tide-marks.

(3.) One of the most striking proofs of upheaval is furnished by what are termed *raised beaches*. A beach is the space between tide-marks, where the sea is constantly busy producing sand and gravel, mingling with them the remains of shells and other organisms, sometimes piling the deposits up, sometimes sweeping them away out into open water. The terrace or platform thus formed is a well-marked feature of coast-lines skirting tidal seas. When the land rises with sufficient rapidity to carry up the line of littoral deposits above the reach of the waves, the flat terrace thus elevated is known as a raised beach. The former high-water mark then lies inland, and while its sea-worn caves are in time hung with ferns and mosses, it furnishes itself an admirable platform, on which meadows, fields, and gardens, roads, houses, villages, and towns spring up, while a new beach is made below the margin of the uplifted one. Raised beaches abound round many parts of the coast-line of Britain. Some excellent examples occur in Cornwall and Devon. The coast-line on both sides of Scotland is fringed with raised beaches, sometimes four or five occurring above each other, at heights of 25, 40, 60, 75 and 100 feet above the present high-water mark. Each terrace marks a former lower level of the land with regard to the sea, and probably a lengthened stay of the land at that level, while the intervals between them represent the vertical amount of each successive uplift of the land, and show that the land in its upward movement did not remain long enough at intermediate points for the formation of terraces. A succession of raised beaches, rising above the present sea-level, may therefore be taken as pointing to a former prolonged upheaval of the country, interrupted by long pauses, during which the general level did not materially change.

(4.) Any stratum of rock containing marine organisms, which have manifestly lived and died where they remain now lie, must be held to prove upheaval of the land. In this way it can be shown that most of the solid land now visible to us has once been under the sea. Even high on the peaks of the cliffs and the flanks of the Himalaya mountains, undoubted marine shells occur in the solid rocks.

(5.) In countries which have been long settled by a human population, it is sometimes possible to prove, or at least to render probable, the fact of recent uprise of the land by reference to tradition, to local names, and to works of human construction. Piers and harbours, if now found to stand above the upper limit of high-water, furnish indeed indisputable evidence of a rise of land since their erection.

§ 2 *Movements of Subsidence.*

It is more difficult to trace the downward movement of the land, for the evidence of each successive sea-margin is carried down and washed away or covered up. Nevertheless, the fact of subsidence can be satisfactorily established by the following kinds of proof² —

(1.) The results of mere erosion by the sea and those of actual depression of the level of the land cannot always be distinguished without some care. The encroachment of the sea upon the land, involving, it may be, the disappearance of successive fields, roads, houses, villages, and even whole parishes, does not necessarily indicate a sinking of the land. Such destruction of the coast-line may, indeed, be in progress without any actual change of level. Should the sea, however, rise to the level of roads and buildings which it never used to touch, should former half-tide rocks cease to show even at low water, and should rocks, previously above the reach of the highest tide, be tunned first into shore reefs, then into skerries and islets, we infer that the coast-line is sinking. Such kind of evidence is found in Scania, the most southerly part of Sweden. Streets, built of course above high-water mark, now lie below it, with older streets lying beneath them, so that the subsidence is of some antiquity. A stone, the position of which had been exactly determined by Linnæus in 1749, was found after 87 years to be 100 feet nearer the water's edge. The west coast of Greenland, for a space of more than 600 miles, is perceptibly sinking. It has there been noticed that, over ancient buildings on low shores, as well as over entire islets, the sea has risen. The Moravian settlers have been more than once driven to shift their boat-places inland, some of the old poles remaining visible under water.

(2.) As the land is brought down within reach of the waves, its characteristic surface-features are, of course, apt to be effaced, so that the submerged area which passes down beneath the sea may retain little or no evidence of its having been a land-surface. It will be covered, as a rule, with sea-worn sand or silt. Hence, no doubt, the reason why, among the marine strata which form so large a part of the stratified portion of the earth's crust, and where there are many proofs of depression, actual traces of land-surfaces are comparatively rare. It is only under very favourable circumstances, as, for instance, where the area is sheltered from prevalent winds and waves, and where, therefore, the surface of the land can sink tranquilly under the sea, that fragments of that surface may be completely preserved under overlying marine accumulations. It is in such places that "submerged forests" occur. These are stumps or roots of trees still in their positions of growth in their native soil. Beds of peat, full of tree-stumps, hazel-nuts, branches, leaves, and other indications of a terrestrial surface, are often found in similar situations. Sir Henry de la Beche has described, round the shores of Devon, Cornwall, and western Somerset, a vegetable accumulation, consisting of plants of the same species as those which now grow freely on the adjoining land, and occurring as a bed at the mouths of valleys, at the bottoms of sheltered bays, and in front of and under low tracts of land, the seaward side of which dips beneath the present level of the sea. Over this submerged land-surface sand and silt containing estuarine shells have generally been deposited, whence we may infer that in the submergence the valleys first became estuaries, and then sea-bays. If now, in the course of ages, a series of such submerged forests should be formed one over the other, and if, finally, they should, by upheaval of the sea-bottom, be once more laid dry, so as to be capable of examination by boring, well-sinking, or otherwise, they

¹ "Earthquakes and Volcanoes," by A. Geikie, Chambers's *Miscellany of Tracts*.

² *Ibid.*

ould prove a former long-continued depression, with intervals of rest. In such a case, the intervals of pause could be marked by the burned forests, and the progress of the depression by the strata of sand and mud lying between them. In short, the evidence would be strictly parallel with that furnished by a succession of raised beaches as to a former protracted elevation with long pauses.

(3.) An interesting kind of proof of an extensive depression of the north-west of Europe is furnished by the deep ords or sea-lochs by which that region is indented. A ord is a long, narrow, and often singularly deep inlet in the sea, which terminates inland at the mouth of a en or valley. The word is Norwegian, and in Norway ords are characteristically developed. The English word fithl," however, is the same, and the western coasts of the British Isles furnish many excellent examples of fjords. In Scotland they are usually called lochs, as Loch Houn, Loch Nevis, Loch Fyne, Gareloch; in Ireland they are sometimes known by the name of loughs, as Lough Foyle, it more commonly by that of bays, as Dingle Bay, Bantry Bay. There can be little doubt that, though now filled with salt water, fjords have been originally land valleys. The long inlet was first excavated as a land-valley or glen. This valley exactly corresponds in form and character with the hollow of the fjord, and must be regarded as merely a inland prolongation. That the glens have been excavated by subaerial agents is a conclusion borne out by great weight of evidence. If, therefore, we admit the subaerial origin of the glen, we must also grant a similar origin to its seaward prolongation. Every fjord will thus mark the site of a submerged valley. This inference is confirmed by the fact that fjords do not, as a rule, occur singly. Like the glens on the land they lie in groups; so that when they are found intersecting a long line of coast, as that of the west of Norway, or the west of Scotland, we conclude that the land has there sunk down so as to permit the sea to run far up and fill the submerged glens.

(4.) Evidence of widespread depression over the area of the Pacific Ocean is furnished by the numerous atolls or coral islands scattered throughout that vast expanse of water. Mr Darwin ascertained that the reef-building corals do not live at a greater depth than about 15 or 20 fathoms. The reefs and circular islets of coral rise with nearly perpendicular sides from a depth of 2000 feet and upwards, until they reach the surface of the sea. As the corals could not have begun to grow upward from such vast depths, Mr Darwin first suggested that the sites of these coral reefs had undergone a progressive subsidence, the rate of upward growth of the reefs keeping pace, on the whole, with the depression. A fringing reef would first be formed fronting a land within the limit of the 20 fathom line. Growing upward until it reached the surface of the water, it would be exposed to the dash of the waves, which would break off pieces of the coral and heap them upon the reef. In this way islets would be formed which, by successive accumulations of materials thrown up by the breakers or brought by winds, would remain permanently above water. On these islets palms and other plants, whose seeds might be drifted on the adjoining land, would take root and flourish. Inside the reef there would be a shallow channel of water, communicating, through gaps in the reef, with the main sea outside. Fringing reefs of this character are of common occurrence at the present time. In the case of a continent they front its coast for a long distance, but they only entirely surround an island. If the site of a fringing reef undergoes depression at a rate sufficiently slow to allow the corals to keep pace with it, the reef will grow upward till the bottom sinks downward. The lagoon channel inside will become deeper and wider, while, at the same time, the

depth of the water outside will increase. In this way a barrier reef will be formed. Continued slow depression must continually diminish the area of the land enclosed within one of these rings of coral-reef, while the reef itself retains much the same size and position. At last the final peak of the original island disappears under the lagoon, and an atoll or true coral island is formed. Should any more rapid or sudden downward movement take place, it might carry the atoll down beneath the surface, as seems to have happened at the Great Chagos bank in the Indian Ocean, which is a submerged atoll. It has recently been suggested that barrier reefs do not necessarily prove subsidence, seeing that they may grow outward from the land upon the top of a talus of their own debris broken down by the waves, and may thus appear to consist of solid coral which had grown upward from the bottom during depression, although only the upper layer, 20 fathoms or thereabouts in thickness, is composed of solid, unbroken, coral growth. The explanation may doubtless account for some barrier-reefs, and for the way in which the steep seaward face of all such reefs is formed and maintained. But it does not elucidate the existence of submerged atolls, the presence of gaps in atolls answering to gaps in the fringing reefs opposite to the mouths of rivers, and the difficulty of supposing that, in a coral archipelago, there should have been scores of submerged peaks so nearly of the same height as to rise within 20 fathoms of the surface, and yet so seldom actually to tower above it. According to the simple and luminous theory of Mr Darwin, every stage in the progress of the changes is open to observation, from the incipient fringing reef to the completed and submerged atoll. Every observed fact fits in harmoniously with the others, and we reach the impressive conclusion that a vast area of the Pacific Ocean, fully 6000 geographical miles from east to west, has undergone a recent subsidence, and may be slowly sinking still.

It by no means follows, however, as some writers have imagined, that the present Pacific Ocean occupies the site of a vast submerged continent. All the coral islands seem to have been built on volcanic peaks. Wherever any non-calcareous rock appears it is of volcanic origin. We must therefore conceive of these oceanic islands as detached volcanic eminences rising out of a wide area of subsidence, and doubtless as deriving their existence from the results of that subterranean movement.

§ 3. Causes of Secular Upheaval and Depression.

These movements, without question, we must again trace back to consequences of the original internal heat of the earth. There are various ways in which the heat may have acted. Thus a considerable accession of heat expands rocks, and, on the other hand, a loss of heat causes them to contract. We may suppose therefore that, during the subterranean changes, a great extent of the crust underneath a tract of land may have its temperature slowly raised. The effect of this increment would be to cause a slow uprise of the ground above. The gradual transference of the heat to another quarter might produce a steady subsidence. Such variations in subterranean temperature, however, could give rise at the most to but very insignificant elevations or depressions.

A far more important and generally effective cause is to be sought in the secular contraction of the globe. If our planet has been steadily losing heat by radiation into space, it must have progressively diminished in volume. The cooling implies contraction. According to Mr Mallet, the diameter of the earth is less by at least 189 miles since the time when the planet was a mass of liquid.¹ But the contraction has not manifested itself uniformly over the whole

¹ *Phil. Trans.*, 1873, p. 250.

surface of the planet. The crust varies much in structure, in thermal resistance, and in the position of its isogeo-thermal lines. As the hotter nucleus contracts more rapidly by cooling than the cooled and hardened crust, the latter must sink down by its own weight, and in so doing requires to accommodate itself to a continually diminishing diameter. The descent of the crust gives rise to enormous tangential pressures. The rocks are crushed, crumpled, and broken in many places. Subsidence must have been the general rule, but every subsidence would doubtless be accompanied with upheavals of a more limited kind. The direction of these upheaved tracts would largely depend upon the original structure of the crust. It would be apt to occur in lines which, once taken as lines of weakness or relief from the intense strain, would probably be made use of again and again at successive paroxysms or more tranquil periods of contraction. Mr Mallet, in the paper already cited, has ingeniously connected these movements with the linear direction of mountain chains, volcanic vents, and earthquake shocks.

Though the origin of the present surface configuration of the land will be more conveniently discussed in a subsequent part of this article, after the structure of the earth's crust has been described, a few words may be inserted here, where some allusion to the subject might be looked for. Mountains may arise from three causes—(1) from the corrugation of the earth's crust due to the effects of secular contraction, (2) from the accumulation of materials poured out of volcanic orifices, and (3) from the isolation of elevated masses of ground, owing to the removal, by denudation, of the materials originally connecting them, and to the consequent formation of valleys. Mountains formed in the volcanic way are almost always conical, and are either solitary, as *Etna*, or occur in linear groups, like the volcanoes of *Java*. Those formed by denudation are of minor dimensions, and rather deserve the name of hills. Mountain-chains, on the other hand, which are the dominant features of the earth's surface, though they may have lines of volcanic vents along their crests, are not formed essentially of volcanic materials, but of the sedimentary and crystalline rocks of the crust which have been ridged up into vast folds. If the continental lands may be compared to great undulations of the solid surface of the globe, the mountain-chains may be likened to the breaking crests of such wave-like undulations. In their internal structure mountain-chains bear witness to the intense crumpling of the rocks during the process of upheaval. As a consequence of the uprising of two or more parallel ranges of mountain, lines of longitudinal valley must be produced. But no sooner is a mass of land raised above the sea than it is exposed to the attacks of air, rain, frost, springs, glaciers, or other meteoric agents of disintegration. Its surface is then worn down, the flow of water down its slopes cuts out gulleys, ravines, and valleys, so that eventually a very rugged surface is produced, on which, probably, no portion of the original surface of upheaval may remain, but where new lines of minor ridge and valley may appear as the combined result of internal geological structure and atmospheric denudation. The reader, however, is referred to part vii. of this article for a fuller treatment of this interesting subject.

During the movements by which mountain masses have been upheaved, the stratified rocks have been so compressed as to occupy, in many cases, but a small proportion of the horizontal extent over which they originally extended. They have adjusted themselves to this diminished area by undergoing intense plication, and thus acquiring a much greater vertical depth. On the other hand, they have been abundantly fractured, some portions of their mass being pushed up, others being let down, so that the crust is

traversed with a kind of complicated network of fissures. The discussion of these features of geological structure, however, must likewise be postponed to part iv., where the facts regarding their occurrence will be described.

Section IV.—Hypogene Causes of Changes in the Texture, Structure, and Composition of Rocks.

The phenomena of hypogene action hitherto under consideration have related almost wholly to the effects produced at the surface. It is evident, however, that these phenomena must be accompanied by very considerable changes in the rocks which form the earth's outer crust. These rocks, as just stated, have been subjected to enormous pressure; they have been contorted, crumpled, and folded back upon themselves, as if thousands of feet of solid limestones, sandstones, and shales had been merely a few layers of carpet, they have been shattered and fractured everywhere; they have in one place been pushed far above their original position, in another depressed far beneath it, so great has been the compression which they have undergone that their component particles have in many places been rearranged, and even crystallized. They have here and there actually been reduced to fusion, and have been abundantly invaded by masses of molten rock from below.

In the present section of this article we shall consider chiefly the nature of the agencies by which such changes have been effected, the results achieved, in so far as they constitute part of the architecture or structure of the earth's crust, will be discussed in part iv. At the outset, it is evident that we can hardly hope to detect many of these processes of subterranean change actually in progress and watch their effects. The very vastness of some of them places them beyond our direct reach, and we can only reason regarding them from the changes which we see them to have produced. But a good number are of a kind which we can in some measure imitate in our laboratories and furnaces. It is not requisite, therefore, to speculate wholly in the dark on this subject. Since the original and classic researches of Sir James Hall, the founder of experimental geology, great progress has been made in the investigation of hypogene processes by experiment. The conditions of nature have been imitated as closely as possible, and varied in different ways, with the result of giving us an increasingly clear insight into the physics and chemistry of subterranean geological changes. The succeeding portions of this section of the article will therefore be chiefly devoted to an illustration of the nature of hypogene action, in so far as that can be inferred from the results of actual experiment. The subject may be conveniently treated under three heads—(1) the effects of heat; (2) the effects of pressure and contraction; (3) the influence of water in effecting changes in minerals and rocks.

§ 1. *Effects of Heat.*

The importance of heat among the transformations of the rocks has been fully admitted by geologists, since it used to be the watchword of the Huttonian or Vulcanist school at the end of last century. Two sources of subterranean heat may have at different times and in different degrees co-operated in the production of hypogene changes—(1) the internal heat of the globe, of which some account has already been given, and (2) the heat due to the transformation of mechanical energy in the crumpling, fracturing, and crushing of the rocks of the crust, as these have been from time to time compelled to adjust themselves to the diminishing diameter of the more rapidly cooling and contracting interior. From which of these two sources, or from what combination of them, the heat was derived by which any given change in the rocks was produced, is a problem which admits

in the meantime of only very partial solution. Leaving this question for the present, let us examine the effects which are clearly referable to the influence of heat. It is evident that the conditions under which these effects are produced must vary almost infinitely. We have to consider (1) the temperature, from the lowest at which any change is possible up to that of complete fusion, (2) the nature of the rock operated upon, some materials being much more susceptible of change from heat than others; (3) the pressure under which the heat acts, the potency of this agency being much increased with increase of pressure; (4) the presence of water, whereby chemical changes take place which would not be possible in dry heat.

In an interesting series of experiments the illustrious De Saussure (1779) fused some of the rocks of Switzerland and France, and inferred from them, contrary to the opinion previously expressed by Desmarest,¹ that basalt and lava have not been produced from granite, but from hornstone (*pietre de corne*), varieties of "schorl," calcareous clays, marls, and micaceous earths, and the cellular varieties from different kinds of slate.² He observed, however, that the artificial products obtained by fusion were glassy and enamel-like, and did not always recall volcanic rocks, though some exactly resembled porous lavas.

Sir James Hall, about the year 1790, began an important investigation, in which he succeeded in reducing various ancient and modern volcanic rocks to the condition of glass, and in restoring them, by slow cooling, to a stony state. Since that time many other researches of a more complicated kind have been undertaken, especially by Delesse, Daubrée, Deville, Bunsen, Busch, H. and W. Rogers. By these observations it has been abundantly proved that all rocks undergo molecular changes when exposed to high temperature, that when the heat is sufficiently raised they become fluid, that if the glass thus obtained is rapidly cooled it remains vitreous, and that, if allowed to cool slowly, a more or less distinct crystallization sets in, the glass is devitrified, and a lithoid product is the result.

Illustrations of the influence of different degrees of heat upon rocks of different kinds may often be very instructively observed at lime-kilns, especially those roughly-built kilns or pits which may still be met with in outlying districts. Some of the stones lining such cavities will be found with no sensible change, others show a somewhat cellular texture, others have acquired a rudely prismatic structure, while some have had their surfaces fused into a rough glaze or enamel. The bricks or stones used for lining furnaces present similar illustrations, the columnar or prismatic structure being occasionally very perfectly developed in these materials. Mere contact with a highly-heated surface, and subsequent gradual cooling, have often produced this prismatic arrangement in rocks of the most diverse kinds. Thus, in Scotland, beds of sandstone and seams of coal have acquired the most perfect prismatic structure from the intrusion of basalt dykes or sheets through them. To these and other effects of intruded igneous rocks reference will be made in the sequel. In these cases the alteration is merely local, and has obviously been produced by contact with a highly heated surface. But, besides such minor effects due merely to contact, others of a more general kind affect large masses of rock or whole districts of country.

When rocks are exposed to temperatures as high as their melting-points, they fuse into glass which, in the great majority of cases, is of a bottle-green or black colour, the depth of the tint depending mainly on the proportion of iron. In this respect they resemble the natural glasses—pitchstones and obsidians. They almost always contain

minute cells or bubbles, arising probably from the disengagement of water or of oxygen during the fusion. But after the most thorough fusion which has been found possible, minute granules usually appear in the solidified glass. Sometimes these consist of specks of quartz, which is especially apt to remain unmelted when the rock is very siliceous, or of other minerals of the original rock. But a microscopic investigation of fused rocks shows that, even in what seems to be a tolerably homogeneous glass, there are abundant minute hair-like, feathered, needle-shaped, or irregularly-aggregated bodies diffused through the glassy paste. These *crystallites* are in some cases colourless silicates, in others they are opaque metallic oxides, particularly oxides of iron. They precisely resemble the crystallites which are observed in many volcanic rocks, such as obsidian, pitchstone, and basalt. They may be obtained even from the fusion of a granitic or granitoid rock, as in the well-known case of the Mount Sorrel syenite near Leicester, which, being fused and slowly cooled, yielded abundant crystallites, including exquisitely grouped octahedra of magnetite.

According to the observations of Delesse, volcanic rocks, when reduced to a molten condition, attack briskly the sides of the Hessian crucibles in which they are contained, and even eat them through. This is an interesting fact, for it helps to explain how some intrusive igneous rocks have come to occupy positions previously filled by sedimentary strata, and why, under such circumstances, the composition of the same mass of rock should be found to vary considerably from place to place.³

It would appear that, in passing from a crystalline into a vitreous condition, rocks undergo a diminution of density, which, on the whole, is greater the more silica and alkali are present, and is less as the proportion of iron, lime, and alumina increases. According to Delesse, granites, quartziferous porphyries, and such highly silicated rocks lose from 8 to 11 per cent. of their density when they are reduced to the condition of glass, basalts lose from 3 to 5 per cent., and lavas, including the vitreous varieties, from 0 to 4 per cent. This diminution of density (and consequent increase of volume) may account for minor oscillations of the ground so often observed in volcanic regions. If we suppose a subterranean mass of lava 500 feet thick to pass from the fluid to the crystalline condition, this might cause a subsidence of the ground above to the extent of about 20 or 25 feet. The transition of a similar mass of rock from the solid to the fluid condition would cause an uprise to a like amount.

So far as experiments have yet been conducted, it has been found impossible to obtain from a piece of fused rock a crystalline substance exactly resembling the original mass. Externally it may appear quite stony, but its internal structure, as revealed by the microscope, shows it to be essentially a slag or glass, and not a truly crystalline rock. There is another fundamental difference between the natural and artificial products. When a compound containing substances of different fusibilities is artificially melted, and allowed thereafter to cool in such a way that the various ingredients may separate from each other, they appear in their order of fusibility, the most refractory coming first, and the most fusible being the last to take a solid form. But in rocks which have crystallized naturally from a fluid condition, it is often to be observed that the component minerals have been far from obeying what might have been supposed to be their invariable law. Thus, in all parts of the world, granite presents the very striking fact that its quartz, which we call an infusible mineral, has actually solidified after the more fusible felspar. In the Vesuvian lavas the

¹ *Mém. Acad. Scien.*, 1771, p. 278.

² De Saussure, *Voyages dans les Alpes*, edit. 1803, tome i. p. 178.

³ *Bull. Soc. Géol. France*, 2d ser., iv. 1382.

difficultly fusible leucite may be seen to have enclosed crystals already formed of the fusible augite. In many ancient crystalline rocks the pyroxenic constituents, which offer a less resistance to fusion, have assumed a crystalline form before the more refractory triclinic feldspars. From these facts it is clear that, in the fusion of rocks and in their subsequent consolidation, there must have been conditions under which the normal order of appearance of the minerals was disturbed or reversed. Yet another fact may be mentioned to show further the difference between the kind of fusion which has frequently obtained in nature and that of the ordinary operations of a glass-work or iron-furnace. As far back as the year 1846 Scheerer showed that there exist in granite various minerals which could not have consolidated save at a comparatively low temperature. He instanced especially several gadolinites, orthites, and allanites, which cannot endure a higher temperature than a dull-red heat without altering their physical characters; and he concluded that granite, though it may have possessed a high temperature, cannot have solidified from simple igneous fusion.

We may conclude, therefore, that the manner in which rocks have been melted within the crust is not that mere simple fusion which we can accomplish artificially, but that it has involved conditions which have not been successfully imitated in any laboratory or furnace. Two obvious differences must occur to the reader between the natural and artificial operations. In the first place, rocks which have undoubtedly once been in a fluid or at least pasty condition, and which have been injected as veins and dykes into previously consolidated masses, contain water imprisoned within their component crystals. This is not water which has been subsequently introduced. It is contained in minute cells, which it usually does not now completely fill, but which it no doubt did occupy completely at the time and temperature at which the rock was consolidated. We have seen (*note*, p. 250) how abundant are the discharges of water-vapour from volcanic fires, how the molten lava-streams issue from their vents, saturated, as it were, with steam, and how the steam continues to rise from them long after they have been cooled and come to rest. In the solid crystals of lava which were erupted only recently, as well as in those of early geological periods, the presence of water in minute cavities may be readily detected. It is in the quartz of such rocks, and still more in that of granite, that the detection of water-cavities is most easily made. The quartz of granite is usually full of them. "A thousand millions," says Mr J. Clifton Ward, "might easily be contained within a cubic inch of quartz, and sometimes the contained water must make up at least 5 per cent of the whole volume of the containing quartz." Thus microscopic investigation confirms the conclusion arrived at by Scheerer in the memoir already cited, that at the time of its eruption granite must have been a kind of pasty mass containing a considerable proportion of water. It is common now to speak of the "aquo-igneous" origin of some eruptive rocks, and to treat their production as a part of what is termed the "hydro-thermal" operations of geology. We may conclude that, while some rocks, like obsidian and pitchstone, which so closely resemble artificial glasses, may have been derived from a simple igneous fusion such as can be imitated in a furnace (though even in these the presence and influence of water may be traced), the great majority of rocks have had a more complex origin, and in a great number of cases can be proved to have been mingled with more or less water while they were still fluid.

In the second place, there can be no question that, in the great hypogene laboratory of nature, rocks have been softened and fused under enormous pressure. Besides the pressure due to their varying depth from the surface, they

must have been subject to the enormous expansion of the superheated water or vapour which filled all their cavities. Mr Sorby has ingeniously estimated the probable pressure under which granite consolidated by taking the ratio between the size of the liquid cavities in the quartz and that of the contained bubble or vacuity. Assuming the temperature of consolidation to have been 680° Fahr. (360° Cent.), or a dull-red heat, he inferred that in many cases the pressure under which the granite consolidates must have been equal to that of an overlying mass of rock 50,000 feet, or more than 9 miles, in thickness. It is not probable that any such thick overlying mass ever did cover the granite, the pressure, even if it be allowed to have been so great, must have been due partly to other causes, such as the compression due to secular contraction.

It would appear therefore that perfect anhydrous fusion, or the reduction of a rock to the state of a completely homogeneous glass, has been a comparatively rare process in nature, or at least that such glasses, if originally formed, have in the vast majority of cases undergone devitrification and crystallization, until the glassy base has been reduced to a smaller or larger fraction of the total mass of the rock, or has entirely passed into a stony condition. In many volcanic rocks the original vitreous base or ground-mass can be readily observed with the microscope between the definitely-formed crystals. Crystallites, or arrested stages in the crystallization of iron oxides and of silicates, can often be detected in these rocks, more especially where it is evident that they must have cooled with comparative rapidity, as where they have been thrust into narrow fissures to form dykes. But in rocks such as granite, where no glass exists, but where the mineral constituents are all crystalline, no trace of the crystallites occurs. Doubtless such differences point to original distinctions in the kind and degree of fusion of the rocks. It seems reasonable to suppose that those rocks which show a glassy ground-mass, and the presence of crystallites, have been fused under conditions more nearly resembling those of the simple igneous fusion of experiment.

It has long been known that many mineral substances can be obtained in a crystalline form from the condensation of vapours. This process, called sublimation, may be the result of the mere cooling and reappearance of bodies which have been vaporized by heat and solidify on cooling, or from the solution of these bodies in other vapours or gases, or from the reaction of different vapours upon each other. These operations are of common occurrence at volcanic vents, and in the crevices of recently erupted and still hot lava-streams. They have been successfully imitated by experiment. In the early researches of Sir James Hall on the effects of heat modified by compression, he obtained by sublimation "transparent and well-defined crystals," lining the unoccupied portion of a hermetically-sealed iron tube, in which he had placed and exposed to a high temperature some fragments of limestone (*Trans. Roy. Soc. Edin.*, vi. 110). Numerous experiments have been made by Messrs Delesse, Daubrée, and others, in the production of minerals by sublimation. Thus many of the metallo-sulphides found in mineral veins have been produced by exposing to a comparatively low temperature (between that of boiling water and a dull-red heat) tubes containing metallic chlorides and sulphide of hydrogen. By varying the materials employed, corundum, quartz, apatite, and other minerals have been obtained. It is not difficult, therefore, to understand how, in the crevices of lava-streams and volcanic cones, as well as in some mineral veins, sulphides and oxides of iron and other minerals may have been formed by the ascent of heated vapours. Superheated steam is endowed with a remarkable power of dissolving that intractable substance, silica; artificially heated to the tem-

perature of the melting point of cast-iron, it rapidly attacks silica, and deposits the mineral in snow-white crystals as it cools.

§ 2 *Effects of Pressure and Contraction*

Besides the influence of pressure in raising the melting point of subterranean rocks, and in permitting water to remain fluid among them at temperatures far above the boiling-point, even at a red or perhaps a white heat, we have to consider the effects produced by the same cause upon rocks already solidified. The simplest and most obvious result of pressure upon such rocks is their consolidation, as where a mass of loose sand is gradually compacted into a more or less coherent stone, or where a layer of vegetation is compressed into peat, lignite, or coal. In many cases the cohesion of a sedimentary rock is due merely to the pressure of the superincumbent strata. But it usually happens that some cementing material has contributed to bind the component particles together. Of these natural cements the most frequent are peroxide of iron, silica, and carbonate of lime.

Pressure equally distributed over a rock presenting everywhere nearly the same amount of resistance will promote consolidation, but may produce no further internal change. If, however, the pressure becomes extremely unequal, or if the rock subjected to it can find escape from the influence in one or more directions, there will be a disturbance or rearrangement of the particles, which by this means are made to move upon each other. Five consequences of these movements may be noticed here.

(1) *Cleavage*.—When a mass of rock, owing to subsidence or any other cause, is subjected to powerful lateral compression, its innate particles, which in all rocks have almost invariably a longer and shorter axis, tend, under the intense strain, to rearrange themselves in the line of least resistance, that is, with their long axes perpendicular to the direction of the pressure. The result of this readjustment is that the rock affected by it acquires a facility for splitting along the lines in which its component particles have placed themselves. Fine-grained argillaceous rocks show most characteristically this internal change; but in coarse materials it becomes less conspicuous, or even disappears. Rocks which have been thus acted on, and have acquired this superinduced fissility, are said to be *cleaved*, and the fissile structure is termed *cleavage*. This has been proved experimentally by Sorby, who produced perfect cleavage in pipeclay through which scales of oxide of iron had previously been mixed. Dr Tyndall superinduced cleavage on bees-wax and other substances by subjecting them to severe pressure. Cleavage among rocks occurs on a great scale in countries where the strata have been greatly plicated, that is, where they now occupy much less horizontal surface than they once did, and consequently where, in accommodating themselves to their diminished area, they have had to undergo much powerful lateral compression. The structure of districts with cleaved rocks is described in part iv.

(2) Further evidence of the compression to which rocks have been subjected is furnished by the way in which contiguous pebbles in a conglomerate may be found to have been squeezed into each other, and even sometimes to have been elongated in a certain general direction. It is doubtless the coarseness of the grain of such rocks which permits the effects of compression to be so readily seen. Similar effects must take place in fine-grained rocks, though they escape observation. Organic remains both of plants and animals may often be found to have undergone considerable distortion from this cause. M. Daurée has imitated experimentally the indentations produced by the contiguous portions of conglomerate pebbles.¹

(3) The ingenious experiments of M. Tresca on the flow of solids have proved that, even at ordinary atmospheric temperatures, solid resisting bodies like lead, cast-iron, and ice, may be so compressed as to undergo an internal motion of their parts which is closely analogous to that of fluids. Thus, a solid jet of lead has been produced by placing a piece of the metal in a cavity between the jaws of a powerful compressing machine. Iron, in like manner, has been forced to flow in the solid state into cavities and take their shape. On cutting sections of the metals so compressed, their particles or crystals are found to have ranged themselves in lines of flow which follow the contour of the space into which they have been squeezed. Such experiments are of considerable geological interest, for they show that in certain circumstances, under great pressure, the unequally mixed particles of rocks within the earth's crust may have been forced to move upon each other, and thus to acquire a "fluid-structure" resembling that which is seen in rocks which have possessed true liquidity. No large sheet of rock can be expected, however, to have undergone this internal change; the effects could only be produced exceptionally at places where there was an escape from the pressure, as, for instance, along the sides of fissures, or in other cavities of rocks. The explanation cannot be applied to the case of rocks like schists, which display a kind of rude foliation or fluid-structure over areas many thousands of square miles in extent.

(4) *Plication*.—Reference has already been made to the fact that, owing to the more rapid contraction of the inner portion of the globe, the outer layer or crust is from time to time forced to adjust itself to this change by subsiding. As a consequence of the subsidence, the descending area requires to occupy less horizontal space, and must therefore suffer powerful lateral compression. The rocks are thus crumpled up, as, in the classic experiment of Sir James Hall, folds of cloth are folded when a weight is placed upon them and they are squeezed from either side. The mere subsidence of such a curved surface as that of our globe must thus necessarily produce much lateral compression. Mr J. M. Wilson has calculated that, if a tract of the earth's surface, 345 miles in breadth, be depressed one mile, it will undergo compression to the extent of 121 yards; at two miles the compression will be 189 yards; at eight miles 598 yards. The observed amount of compression in districts of contorted rocks, however, far exceeds these figures. Another cause of the compression and contortion of rocks is the injection into them of igneous masses from below, but this is probably a minor source of disturbance. The character of plicated rocks is described in part iv. p. 300.

(5) *Faults*.—Closely connected with the disturbances which have produced contortions come those by which the crust of the earth has been fractured. But in this case the movement is one of elevation rather than of subsidence; for, instead of having to occupy a diminished diameter, the rocks get more room by being pushed up, and as they cannot occupy the additional space by any elastic expansion of their mass, they can only accommodate themselves to the new position by a series of dislocations. Some portions will be pushed up farther than others, and this will happen more particularly to those which have a broad base. These will rise more than those with narrow bottoms, or the latter will seem to sink relatively to the former. Each broad-bottomed segment will thus be bounded by two sides sloping towards the upper part of the block. This is found to be almost invariably the case in nature. A fault or dislocation is nearly always inclined from the vertical, and the side to which the inclination rises, and from which it "hades," is the upthrow side. The details of these features of geological structure are discussed in part iv., section v.

§ 3. *Influence of Water*

In the great geological contest fought at the beginning of the century between the Neptunists and the Plutonists, the two great battle-cries were, on the one side, Water, on the other, Fire. The progress of the science since that time has shown that each of the parties had truth on its side, and had seized one aspect of the problems touching the origin of rocks. If subterranean heat has played a large part in the construction of the materials of the earth's crust, water, on the other hand, has performed a hardly less important share of the task. They have often co-operated together, and in such a way that the result must be regarded as their joint achievement, wherein the respective share of each can hardly be exactly apportioned. In the following brief résumé of this subject we shall consider the changes produced by pure water, by water charged with substances in solution, and by water raised above ordinary temperatures.

By numerous observations it has been proved that all rocks within the accessible portion of the earth's crust contain interstitial water, or, as it is sometimes called, quarry-water (*eau-de-carrière*). This is not chemically combined with their mineral constituents, but merely retained in their pores. Most of it evaporates when the stone is taken out of the parent rock and freely exposed to the atmosphere. The absorbent powers of rocks vary greatly, and chiefly in proportion to their degree of porosity. Gypsum absorbs from about 0.50 to 1.50 per cent. of water by weight, granite, about 0.37 per cent., quartz from a vein in granite, 0.08, chalk, about 20.0; plastic clay, from 10.5 to 24.5. These amounts may be increased by exhausting the air from the specimens and then immersing them in water.

The water enclosed within the interstices and crystals of igneous rocks may be either an original constituent, deriving its origin, like any of the component minerals, from molten reservoirs within the earth's crust, or it may have descended from the surface to the incandescent rocks. Many facts may be adduced in support of the greater probability of the second view. Besides the general proximity of volcanic orifices to large sheets of water, we have abundant evidence of the actual descent of water from the surface, both through fissures, and also by permeation through the solid substance of rocks. All surface rocks contain water, and no mineral substance is strictly impervious to the passage of liquid. The well-known artificial colouring of agates proves that even the mineral substances apparently most homogeneous and impervious can be traversed by liquids. M. Daubrée has instituted a series of experiments to illustrate the power possessed by water of penetrating rocks, in virtue of their porosity and capillarity, even against a considerable counter-pressure of vapour, and, without denying the presence of original water, he concludes that the interstitial water of igneous rocks may all have been derived by descent from the surface.

The presence of interstitial water must affect the chemical constitution of rocks. It is now well understood that there is probably no terrestrial substance which, under proper conditions, is not to some extent soluble in water. By an interesting series of experiments, made many years ago by Messrs Rogers, it was ascertained that many of the ordinary mineral constituents of rocks could be dissolved to an appreciable extent even by pure water, and that the change was accelerated and augmented by the presence of carbonic acid.¹ Silica, alkaliiferous silicates, and iron oxides can be taken up and held in solution by pure water, even at ordinary temperatures, in considerable quantities.

The mere presence of pure water therefore within the pores of subterranean rocks cannot but give rise to changes in the composition of these rocks. Some of the more soluble materials must be dissolved, and, as the water evaporates, must be redeposited in a new form.

But water in a natural state is never chemically pure. In its descent through the air it absorbs oxygen and carbonic acid, besides other impurities (see p. 267), and as it filters through the soil it abstracts more carbonic acid, as well as other results of decomposing organic matter. It is thus enabled to effect numerous decompositions of the rocks underneath. The nature of these changes may be inferred from the composition of spring water, to which reference will subsequently be made (p. 270). For the present it will be sufficient to remark that two important kinds of chemical decomposition must evidently arise from the action of such infiltrating water. (1.) The presence of the organic matter must exercise a reducing power on oxides. This will be more especially the case with those of iron, the nearly insoluble hæmatite being reduced to the protoxide, which, converted into carbonate, is readily removable in solution. There can be little doubt that by this means a vast amount of ferruginous matter is extracted from subterranean rocks and carried to the surface. (2.) The presence of carbonic acid enables the water to attack vigorously the mineral constituents of rocks. Alkaline carbonates, with carbonates of lime and magnesia, and protoxides of iron and manganese, are produced, and these substances borne onward in solution give rise to further reactions among the rocks through which they are carried. "In the decomposition of rocks," says Bischof, "carbonic acid, bicarbonate of lime, and the alkaline carbonates bring about most of the decompositions and changes in the mineral kingdom."

The microscopic study of rocks has thrown much light upon the mineralogical alterations in rocks due to the influence of percolating water. Even the most solid-looking, unweathered rocks, are found to have been affected by such metamorphism. Their hydrous magnesian silicates, for example, are partially or wholly converted into such hydrous forms as serpentine, chlorite, or deslessite. The process of conversion may often be watched. It can be seen to have advanced along the fissures or cleavage-planes of the minerals leaving the intervening sections still fresh; or it may be observed to have proceeded in such a way that diffused alteration-products are dispersed in filaments or irregular patches through the base of the rock, or gathered together and even recrystallized in cavities; or the whole rock, as in many serpentine, has undergone an entire transformation. Much information regarding such internal alterations of rocks may be obtained from the study of *pseudomorphs*, that is, crystals having the external form of the mineral of which they originally consisted, with the internal structure and composition of the mineral which has replaced it. Serpentine representing olivine, clay taking the place of rock-salt, silica that of wood, and marcasite that of molluscan shell, are familiar examples. There is no reason to doubt that these changes may, in the course of ages, have been effected at ordinary temperatures by water descending from the surface of the ground.

But two other considerations require to be taken into account in the discussion of the internal transformations of rocks by subterranean water. (1.) In the first place, the water has often been at a high temperature. Mere descent into the crust of the earth will raise the temperature of the water until, if this descent be prolonged, a point far above 212° Fahr. may be reached. Experiments have shown that the chemical action of water is vastly increased by heat. Thus M. Daubrée exposed a glass tube containing about half

¹ *American Journal of Science* (2), v. 401.

its weight of water to a temperature of about 400° C. At the end of a week he found the tube so entirely changed into a white, opaque, powdery mass as to present not the least resemblance to glass. The remaining water was highly charged with an alkaline silicate containing 63 per cent. of soda and 37 per cent. of silica, with traces of potash and lime. The white solid substance was ascertained to be composed almost entirely of crystalline materials. These consisted partly of minute perfectly limpid bipyramidal crystals of quartz, but chiefly of very small acicular prisms of wollastonite. It was found, moreover, that the portion of the tube which had not been directly in contact with the water was as much altered as the rest, whence it was inferred that at these high temperatures and pressures the vapour of water acts chemically like the water itself. (2) In the second place, the effect of pressure must be recognized as most important in enabling water, especially when heated, to dissolve and retain in solution a larger quantity of mineral matter than it could otherwise do. In M. Daubrée's experiments just cited, the tubes were hermetically sealed and secured against fracture, so that the pressure of the greatly super-heated vapour had full effect. By this means, with alkaline water, he not only produced the two minerals above mentioned, but also feldspar and diopside.

It is important to observe that the three conditions required for these changes—the presence of alkaline water, a high temperature, and considerable pressure—are precisely those which it can be affirmed must exist abundantly within the crust of the earth. We must admit the possibility of rocks originally at the surface being depressed so as to come within the influence of internal heat, and to contain within their pores abundant interstitial water more or less charged with alkaline carbonates. Rocks under these conditions, so far as we can judge, can hardly escape internal decomposition and recombination. Mere descent to a great depth beneath the surface will not necessarily result in metamorphism, as has been shown in the case of the Nova Scotian and of the South Welsh coal-field, where sandstones, shales, clays, and coal-seams can be proved to have been once depressed 14,000 to 17,000 feet below the sea-level, under an overlying mass of rock, and yet to have sustained no serious alteration. Perhaps the failure of change may be explicable on the supposition that these Carboniferous strata were comparatively dry. But where rocks possess sufficient interstitial water, and are depressed within the crust so as to be exposed to a considerable temperature and to great pressure, they must be metamorphosed,—the extent of the metamorphism depending partly upon the vigour of the attack made upon them by the water, partly on their own composition and proneness to chemical change, and partly upon the length of time during which the process is continued.

A metamorphosed rock must thus be one which has suffered a mineralogical rearrangement of its substance. It may or may not have been a crystalline rock originally. Any rock capable of alteration (and all rocks must be so in some degree) will, when subjected to the required conditions, become a metamorphic rock. The resulting structure, however, will, in most cases, bear witness to the original character of the mass. A sedimentary rock, for example, consisting of alternate layers of different texture and composition, will doubtless retain, even in its metamorphosed condition, traces of that fundamental structure. The water will travel more easily along certain layers than along others; some laminae will be more readily affected, or will give rise to a set of reactions different from those of contiguous layers. Hence the rearrangement and recrystallization due to metamorphism will take place along the predetermined lines of stratification, so long as these lines have not been effaced or rendered inoperative by any other geo-

logical structure. It is doubtless to this cause that the foliated character of gneiss, mica-schist, and so many other metamorphic rocks is to be ascribed.

In the process of metamorphism, therefore, as well as in that of fusion, to which reference has already been made, the influence of water would seem to have been always conspicuous. Indeed, as will be shown in part iv., it is extremely difficult in many cases to draw a line between the results of metamorphism and igneous fusion, or to decide whether a rock should be called igneous or metamorphic. It has been pointed out above, for example, that in many rocks which have undoubtedly been in a fluid condition, as proved by their injected veins and dykes, the constituent minerals have not appeared in the order of their respective fusibilities. Scheerer, Elie de Beaumont, and Daubrée have shown how the presence of a comparatively small quantity of water in such rocks has contributed to suspend their solidification, and to promote the crystallization of their silicates at temperatures considerably below the point of fusion. In this way the solidification of quartz in granite after the crystallization of the silicates, which would be unintelligible on the supposition of mere dry fusion, becomes explicable. The phenomena of metamorphism in the architecture of the earth's crust are discussed in part iv.

DIVISION II.—EPIGENE OR SURFACE ACTION

It is on the surface of the globe and by the operation of agents working there that at present the chief amount of visible geological change is effected. In considering this branch of inquiry, we are not involved in the same preliminary difficulty regarding the very nature of the agencies as we found to be the case in the investigation of plutonic action. On the contrary, the surface agents are carrying on their work under our very eyes. We can watch it in all its stages, measure its progress, and mark in many ways how accurately it represents similar changes which for long ages previously must have been effected by the same means. But in the systematic treatment of this subject we encounter a difficulty of another kind. We discover that while the operations to be discussed are numerous and often complex, they are so interwoven into one great network that any separation of them under different subdivisions is sure to be more or less artificial, and to convey an erroneous impression. While, therefore, under the unavoidable necessity of making use of such a classification of subjects, we must bear always in mind that it is employed merely for convenience, and that in nature superficial geological action must be continually viewed as a whole, since the work of each agent has constant reference to that of the others, and is not properly intelligible unless that connexion be kept in view.

The movements of the air; the evaporation from land and sea; the fall of rain, hail, and snow, the flow of rivers and glaciers; the tides, currents, and waves of the ocean; the growth and decay of organized existence, alike on land and in the depths of the sea;—in short, the whole circle of movement, which is continually in progress upon the surface of our planet, are the subjects now to be examined. It would be desirable to adopt some general term to embrace the whole of this range of inquiry. For this end the word *epigene* may be suggested as a convenient term, and antithetical to *hypogene* or *subterranean* action.

The simplest arrangement of this part of Geological Dynamics will be into three sections:—

- I. AIR.—The influence of the atmosphere in destroying and forming rocks.
- II. WATER.—The geological functions of the circulation of water through the air and between sea and land, and the action of the sea.

III. LIFE.—The part taken by plants and animals in preserving, destroying, or reproducing geological formations.

The words destructive, reproductive, and conservative, employed in describing the operations of the epigene agents, do not necessarily imply that anything useful to man is destroyed, reproduced, or preserved. On the contrary, the destructive action of the atmosphere may turn barren rock into rich soil, while its reproductive effects sometimes turn rich land into barren desert. Again, the conservative influence of vegetation has sometimes for centuries retained as barren morass what might otherwise have become rich meadow or luxuriant woodland. The terms, therefore, are used in a strictly geological sense, to denote the removal and re-deposition of material, and its agency in preserving what lies beneath it.

Section I.—Air.

Its composition having been already treated of (*ante*, p. 220), we shall consider here (1) the motions, and (2) the geological action of the air, which arises partly from its composition, and partly from its movements.

I. MOVEMENTS OF THE AIR.

These are due to differences in the pressure or density of the atmosphere, the law being that the air always moves from where the pressure is high to where it is low. Atmospheric pressure is understood to be determined by two causes, temperature and aqueous vapour.

1. *Temperature*.—Warm air, being less dense than cold air, ascends, while the latter flows in to take its place. The unequal heating of the earth's surface, by causing upward currents from the warmed portions, produces horizontal currents from the surrounding cooler regions inwards to the central ascending mass of heated air. To this cause the trade winds and the familiar land and sea breezes are due.

2. *Aqueous Vapour*.—In proportion as the quantity of watery vapour increases, the density of the air lessens. Consequently moist air tends to rise as warmed air does, with a corresponding but often very violent inflow of the drier and consequently heavier air from the surrounding tracts. The ascent of the moist air lessens the atmospheric pressure, which is indicated by the fall of the barometer. When the up-streaming vapour rises into the higher regions of the atmosphere, it expands and cools, condensing into visible form, and descending in copious showers to the earth. Unequal and rapid heating of the air, or accumulation of aqueous vapour in the air, and possibly some other influences not yet properly understood, give rise to extreme disturbances of pressure, and consequently to storms and hurricanes. For instance, the barometer sometimes indicates in tropical storms a fall of an inch and a half in an hour, showing that somewhere about a twentieth part of the whole mass of the atmosphere has in that short space of time been displaced over a certain area of the earth's surface. No such sudden change can occur without resulting in the most destructive tempest or tornado. In Britain the tenth of an inch of barometric fall in an hour is regarded as a large amount, such as only accompanies great storms.¹ When the pressure of the air at one place is shown by the barometer to differ from that at a neighbouring locality at the same time, the wind will be observed to move on the whole from the area of high to the area of low pressure; and if the difference be great or sudden, the movement of the air may rise to the force of a hurricane until the equilibrium of pressure is restored.

The meteorological conditions of the atmosphere do not

belong to the scope of this article (see *ATMOSPHERE, CLIMATE, METEOROLOGY*). The reader, however, may note as of interest from a geological point of view the ascertained velocity and pressure exercised by the air in motion across the surface of the earth as expressed in the subjoined table:—

	Velocity in miles per hour.	Pressure in pounds per square foot.
Calm . . .	0	0
Light breeze . .	14	1
Strong breeze.	42	9
Strong gale . .	70	25
Hurricane .	84	36

II. GEOLOGICAL INFLUENCES OF THE AIR.

The paramount importance of the atmosphere as the vehicle for the circulation of temperature and moisture over the globe, and consequently as powerfully influencing the distribution of climate and the growth of plants and animals, must be fully recognized by the geologist. Attention will be confined at present to the direct changes produced on the surface of the earth by the air—(1) on land, and (2) on water.

1. Its Influence on Land.

I. *DESTRUCTIVE INFLUENCES*.—These are either (a) chemical or (β) mechanical, though in nature the two kinds of action are often inseparably interwoven.

(a) Under the denomination of *chemical changes* we include the oxidation of those minerals which can contain more oxygen, as in the peroxidation and precipitation by rocks, and the production of alkaline and earthy carbonates and bicarbonates, which still further promote the process of decomposition. In the one case the active agent of change is the oxygen of the air, or rather of the aqueous vapour in the air, for perfectly dry air seems to have little or no oxidizing effect. A familiar illustration is afforded by the rust, or oxide, which forms on iron when exposed to moisture, though this iron may be kept long bright if allowed to remain screened from moist air. In the other case, the active agent is the carbonic acid of the air, though here again it appears to be requisite that moisture should intervene as the medium of introducing the acid to the substance which is to be altered by it. The occurrence of sulphuric and nitric acids in the air, especially noticeable in large towns, likewise leads to considerable corrosion of metallic surfaces, as well as of stones and lime. The mortar of walls may often be observed to be slowly swelling out and dropping off, owing to the conversion of the lime into sulphate. Great injury is likewise done from a similar cause to marble monuments in exposed graveyards.

As a rule, the changes effected by the air lead to many subsequent transformations. For example, the oxidation of the bisulphide of iron produces sulphuric acid, which decomposes silicates, carbonates, and other compounds with which it comes in contact. These changes, however, are more appropriately noticed under the head of rain (p. 267).

(β) Among the more recognizable *mechanical changes* of a destructive kind, brought about by the atmosphere, we may notice the following influences:—

1. *Expansion and Contraction*.—The effect of heat is to expand rocks, of cold to contract them. Strictly speaking, these results on the surface of the earth are due, not to the air, but to the heat-rays of the sun which reach the rocks through the air. In countries with a great annual range of temperature considerable difficulty is sometimes experienced in selecting building materials liable to be little affected by the alternate expansion and contraction which prevents the joints of masonry from remaining close and

¹ Buchanan's *Meteorology*, p. 266.

tight. In the United States, for example, with an annual thermometric range of more than 90° Fahr. this difficulty led to some experiments by Colonel Totten on the amount of expansion and contraction in different kinds of building-stones, caused by variations of temperature. It was found that in fine-grained granite the rate of expansion was .00004825 for every degree Fahr. of increment of heat, in white crystalline marble it was .000005668, and in red sandstone .000009332, or about twice as much as in granite. If the daily variations in temperature are large, the effects are still more striking. In tropical climates with intensely hot days and extremely cold nights, the rapid nocturnal contraction produces sometimes a strain so great as to rival frost in its influence upon the surface of exposed rocks, disintegrating them into sand, or causing them to crack or peel off in skins or irregular pieces. Dr Livingstone found in Africa (12° S lat, 34° E. long.) that surfaces of rock which during the day were heated up to 137° Fahr. cooled so rapidly by radiation at night that, unable to sustain the strain of contraction, they split and threw off sharp angular fragments from a few ounces to 100 or 200 lb in weight.¹

2. *Frost*—Though properly belonging to the subject of the geological behaviour of water to be afterwards described in more detail, the disintegrating action of frost may be noticed here. In freezing water expands, and thereby exerts an enormous strain upon any enclosed cavities or walls which may confine it. The consequence of this action is that in countries exposed to frost a continual disintegration of the surface of rocks goes on. This superficial decay combines with the chemical and mechanical operations of the atmosphere to produce considerable modifications in the forms of rocks and cliffs.

3. *Wind*—By driving loose sand over rocks, prevalent winds produce on them a scratched and polished surface, as has happened with ancient monuments buried in the sands of the African deserts.² It is said that at Cape Cod holes have even been drilled in window glass by the same agency.³ Cavities are now and then hollowed out of rocks by the gyration in them of little fragments of stone or grains of sand kept in motion by the wind. Hurricanes form important geological agents upon land in uprooting trees, and thus sometimes impeding the drainage of a country, and giving rise to the formation of peat mosses.

Weathering of Rocks.—Under the term "weathering" are included all the superficial changes which rocks undergo in consequence of the action of atmospheric processes upon them. The nature and rapidity of the disintegration depend partly on the one hand upon the climate, and partly on the other upon the composition, texture, and exposure of the rocks. In very dry countries, where the range of temperature is not extreme, weathering is reduced to a minimum. But even if the climate be dry, considerable disintegration may be caused, as has been already explained, by rapid changes of temperature between day and night. It is where moisture prevails, however, that weathering chiefly takes place. The nature of the changes will be more properly considered in the section which is devoted to the action of rain.

II. *REPRODUCTIVE INFLUENCES.*—These arise partly from the result of the chemical and mechanical disintegration involved in weathering, and partly from the transporting power of winds and aerial currents. Under the former head is the formation of soil, under the latter may be noticed the production of sand-hills, the fall of dust-showers and coloured rain, and the transport of seeds.

Soil.—Of the detritus produced by the action of the air on rocks, and washed away by rains and streams, part remains on the land and forms soil. All soil may be considered as the result of the decomposition of rocks, mingled with decayed vegetable and animal matter. Were it not for the action of rain in washing the loose materials to a greater or less distance from their source, the soil of every locality ought to be merely the decayed upper surface of the rocks underneath. But wherever rain falls, the soil is moved from higher to lower levels. Hence in some cases a good soil is laid down upon rocks which of themselves would only produce a poor one. This action of rain in the formation of soil is further alluded to on p. 270, and the co-operative influence of plant and animal life on p. 289.

Sand-hills or Dunes.—Winds blowing continuously upon loose materials, such as sand, drive them onward, and pile them into irregular heaps and ridges, called "dunes." This takes place more especially on windward coasts either of the sea or of large inland lakes, where the shores are sandy; but similar effects may be seen even in the heart of a continent, as in the sandy deserts of the Sahara and of Arabia. The dunes travel inland in parallel, irregular, and often confluent ridges, between which rain-water is some times arrested to form pools (*étangs* of the French coasts), where formations of peat occasionally take place. On the coast of Gascony the sea for 100 miles is so barred by sand-dunes that in all that distance only two outlets exist for the discharge of the drainage of the interior. As fast as one ridge is driven away from a beach another forms in its place, so that a series of huge sandy billows, as it were, is continually on the move from the sea margin towards the interior. A stream or river may temporarily arrest their progress, but eventually they push the obstacle aside or in front of them. In this way the river Adour, on the west coast of France, has had its mouth shifted two or three miles. Occasionally, as at the mouths of estuaries, the sand is blown across so as gradually to exclude the sea, and thus to aid the fluvialite deposits in adding to the breadth of the land.⁴ The coast of Norfolk is fringed with sand-hills 50 to 60 feet high. On parts of the coast of Cornwall, the sand consists mainly of fragments of shells and corallines, and through the action of rain becomes sometimes indurated into a compact stone by carbonate of lime or oxide of iron. Long tracts of blown sand are likewise found along many parts of the Scottish and Irish coast-lines.

On the western border of the European continent extensive sand-dunes exist. They extend for many leagues along the French coast, and thence, by Flanders and Holland, round to the shores of Courland and Pomerania. In Denmark they are said to cover an area of 260 square miles. On the coast of Holland they are sometimes, though rarely, 260 feet high,—a common average height being 50 to 60 feet. The breadth of this maritime belt of sand varies considerably. On the east coast of Scotland it ranges from a few yards to 3 miles; on the opposite side of the North Sea it attains on the Dutch coast sometimes to as much as 5 miles. The rate of progress of the dunes towards the interior depends upon the wind, the direction of the coast, and the nature of the ground over which they have to move. On the low and exposed shores of the Bay of Biscay, when not fixed by vegetation, they travel inland at a rate of about 16½ feet; in Denmark at from 3 to 2½ feet per annum. In the course of their march they envelop

¹ Livingstone's *Zandeen*, pp. 492, 518.

² For an account of this action of drifting sand in North America see Blake in *Pacific Railroad Report*, v. 92, 230.

³ Dana's *Manual*, p. 631.

⁴ For accounts of sand-dunes, their extent, progress, structure, and the means employed to arrest their progress, the reader may consult Andersen's *Kilformationen*, 1 vol. 8vo, Copenhagen, 1891; Lavril in *Annales des Ponts et Chaussées*, 1847, 5me sem., and Marsh's *Man. and Nature*, 1884, and the works cited by him. See also Elie de Beaumont, *Leçons de Géologie*, vol. 1.

houses and fields; even whole parishes and districts once populous have been overwhelmed by them.¹

Along the margins of large lakes and inland seas many of the phenomena of an exposed sea-coast are repeated, and on no inferior scale. Among these must be included sand-dunes, such as occur at the south-eastern end of Lake Michigan and on the eastern borders of the Caspian Sea. The shifting of vast waves of sand by the wind is exemplified on the grandest scale in the sandy deserts of Africa, Arabia, and Central Asia. Such arid wastes of loose sand, situated far inland and far distant from any sheet of fresh water, suggest curious problems in physical geography. Their sites may have been at a comparatively recent geological period covered by the sea; or, lying in rainless climates and having their surfaces exposed to the disintegrating effects of great extremes of temperature, the tracts may have become sandy and barren through atmospheric disintegration. The desert of the Sahara furnishes a good illustration of a dried-up sea-bed. In the rainless tract to the east of the Red Sea lie the great sandy deserts and hills of Arabia, of which Mr Palgrave has given so graphic a narrative. Captain Sturt found vast deserts of sand in the interior of Australia, with long lines of dunes 200 feet high, united at the base and stretching in straight lines as far as the eye could reach. In the south-east of Europe great tracts of sandy desert occur in Poland, and run through the southern provinces of Russia.

Dust-showers, Blood-rain.—In tropical countries, where great droughts are succeeded by violent hurricanes, the dust or sand of dried lakes or river-beds is sometimes borne away into the upper regions of the atmosphere, where, meeting with strong aerial currents which transport it for hundreds and even thousands of miles, it may descend again to the surface, in the form of "red-fog," "sea-dust," or "sirocco-dust." This transported material, usually of a brick-dust or cinnamon colour, is occasionally so abundant as to darken the air and obscure the sun, and to cover the decks, sails, and rigging of vessels which may even be hundreds of miles from land. Rain falling through such a dust-cloud mixes with it, and descends either on sea or land as what is popularly called "blood-rain." This is frequent on the north-west of Africa, about the Cape Verd Islands, in the Mediterranean, and over the bordering countries. A microscopic examination of this dust by Ehrenberg led him to the belief that it contains numerous diatoms of South American species; and he inferred that a dust-cloud must be swimming in the atmosphere, carried forward by continuous currents of air in the region of the trade-winds and anti-trades, but suffering partial and periodical deviations. But much of the dust must come from the sandy plains and desiccated pools of the north of Africa. Daubr e recognized in 1865 some of the Sahara sand which fell in the Canary Islands. On the coast of Italy a film of sandy clay, identical with that in parts of the Libyan desert, is occasionally found on windows after rain. In the middle of last century an area of northern Italy, estimated at about 200 square leagues, was covered with a layer of dust which in some places reached a depth of one inch. Should the travelling dust encounter a cooler temperature, it may be brought to the ground by snow, as has happened in the north of Italy, and more notably in the east and south-east of Russia, where the snows are sometimes rendered dirty by the dust raised by the winds on the Caspian steppes. It is easy to see that a prolonged continuance of this action must give rise to widespread deposits of dust, mingled with the soil of the land, and with the silt and sand of lakes, rivers,

and the sea; and that the minutest organisms of tropical regions may thus come to be preserved in the same formations with the terrestrial or marine organisms of temperate latitudes.²

Transportation of Seeds.—Besides the transport of dust and minute organisms for distances of many thousands of miles, the same agency may come into play also in the transport of living seeds, which, finally reaching a congenial climate and soil, may take root and spread. We are yet, however, very ignorant as to what extent this cause has actually operated in the establishment of any given local flora. With regard to the minute forms of vegetable life, indeed, there can be no doubt as to the efficacy of the wind to transport them across vast distances on the surface of the globe. Upwards of 300 species of diatoms have been found in the deposits left by dust-showers. Among the millions of organisms thus transported it is hardly conceivable that some should not fall into a fitting locality for their continued existence and the perpetuation of their species.

2. Influence of the Air on Water.

The action of the air upon water will be more fully noticed in the section devoted to water (p. 285). It will be enough to notice here—

1. *Ocean Currents.*—The in-streaming of air from cooler latitudes towards the equator causes a drift of the sea-water in the same direction. Owing to the rotation of the earth, these aerial currents tend to take a more and more westerly trend as they approach the equator. This they communicate to the marine currents, which, likewise moving into regions having a greater velocity of rotation than their own, are all the more impelled in the same westerly direction. Hence the westerly belt or equatorial current, which flows across the great ocean. Owing to the position of the continents across its path, this great current cannot move uninterruptedly round the earth. It is split into branches which turn to right and left, and, bathing the shores of the land, carry some of the warmth of the tropics into more temperate latitudes.

2. *Waves.*—The impulse of the wind upon a surface of water throws that surface into pulsations which range in size from mere ripples to huge billows. Long-continued gales from the seaward upon an exposed coast indirectly effect much destruction, by the formidable battery of billows which they bring to bear upon the land. Wave-action is likewise seen in a marked manner when wind blows strongly across a broad inland sheet of water, such as Lake Superior. (See p. 279.)

3. *Alteration of the Water-level.*—When the wind blows freshly for a time down a lake or into a bay or arm of the sea, it drives the water before it, and keeps it temporarily at a higher level, at the further or windward side. In a tidal sea, such as that which surrounds Great Britain, and which sends abundant long arms into the land, this action can often be studied. It is no infrequent occurrence that a high tide and a gale should happen at the same time. Whenever that takes place, then at those bays or firths which look windward the high tide rises to a greater height than elsewhere. With this conjunction of wind and tide, considerable damage to property has sometimes been done by the flooding of warehouses and stores, while even a sensible destruction of cliffs and sweeping away of loose materials may be chronicled by the geologist. On the other hand, a wind from the opposite quarter will drive the water out of the inlet, and thus make the water-level lower than it should otherwise be.

¹ This destruction has been, during the last quarter of a century, reverted to a great extent by the planting of pine forests, the turpentine of which has become the source of a large revenue.

Section II—Water.

Of all the terrestrial agents by which the surface of the earth is geologically modified, by far the most important is water. When following hypogean changes in a foregoing part of this article, we found how large a share is taken by water in the phenomena of volcanoes and other subterranean movements. When we returned to the surface of the earth and began to watch the operations of the atmosphere, we saw how impossible it is to consider these apart from the action of the aqueous vapour by which the atmosphere is pervaded. We must now study in detail the working of this wonderful geological agent itself.

The substance which we term water exists on the earth in three well-known forms—(1) gaseous, as invisible vapour; (2) liquid, as water; and (3) solid, as ice. The gaseous form has already been noticed in our inquiry into the geological characteristics of the air. It is in the air that this condition of the water-substances prevails. By the sun's heat vast quantities of vapour are continually raised from the surface of the seas, rivers, lakes, snow-fields, and glaciers of the world. This vapour remains invisible until the air containing it is cooled down to below its dew-point, or point of saturation,—a result which follows upon the union or collision of two aerial currents of different temperatures, or the rise of the air into the upper cold regions of the atmosphere, where it is chilled by expansion, by radiation, and by contact with cold mountains. At first minute particles appear, which either remain in the liquid condition, or, if the temperature is sufficiently low, are at once frozen into ice. As these changes take place over considerable spaces of the sky, they give rise to the phenomena of clouds. Further condensation augments the size of the cloud-particles, and at last they fall to the surface of the earth, if still liquid, as rain, if solid, as snow or hail; and if partly solid and partly liquid, as sleet. As the vapour is largely raised from the ocean surface, so in great measure it falls back again directly into the ocean. A considerable proportion, however, descends upon the land, and it is this part of the condensed vapour which we have now to follow. Upon the higher elevations it falls as snow, and gathers there into snow-fields, which, by means of glaciers, send their drainage down towards the valleys and plains. Elsewhere it falls chiefly as rain, some of which sinks underground to gush forth again in springs, while the rest pours down the slopes of the land, feeding brooks and torrents, which, swollen further by the springs, gather into broader and yet broader rivers, whereby the drainage of the land is carried out to sea. Thence once more the vapour rises to reappear in clouds, and feed the innumerable water-channels by which the land is furrowed from mountain-top to sea-shore.

Here then is a vast system of circulation, ceaselessly renewed. And in that system there is not a drop of water which is not busy with its allotted task of changing the face of the earth. When the vapour ascends into the air it is almost chemically pure. But when, after being condensed into visible foam, and working its way over or under the surface of the land, it once more enters the sea, it is no longer pure, but more or less loaded with material taken by it out of the air, rocks, or soils through which it has travelled. Day by day the process is advancing. So far as we can tell, it has never ceased since the first shower of rain fell upon the earth. We may well believe, therefore, that it must have worked marvels upon the surface of our planet in past time, and that it may effect vast transformations in the future. As a foundation for such a belief let us now inquire what it can be proved to be doing at the present time.

The subject of the geological operation of water upon

the globe may be conveniently studied under the following subdivisions—

A. TERRESTRIAL WATERS.—Under this head are to be considered—(1) the liquid state, including rain, underground water, brooks, rivers, and lakes, and (2) the solid state—frost, river-ice, snow, hail, glaciers.

B. OCEANIC WATERS.—Including the influence of marine currents, tides, and waves, and the part taken by the sea in the general geological régime of the earth.

A. TERRESTRIAL WATERS.

I. IN THE LIQUID STATE

§ 1. Rain.

Rain effects two kinds of changes upon the surface of the land. (1.) It acts *chemically* upon soils and stones, and sinking under ground continues, as we shall find, a great series of similar reactions there. (2.) It acts *mechanically*, by washing away loose materials, and thus powerfully affecting the contours of the land.

I. CHEMICAL ACTION.—This depends mainly upon the nature and proportion of the substances abstracted by rain from the air in its descent to the earth. Rain always absorbs a little air, and as we have already seen (p. 220) air always contains carbonic acid as well as other ingredients, in addition to its nitrogen and oxygen. If rain be regarded as an agent washing the air and taking impurities out of it, we may the better realize how by means of these it is enabled to work many chemical changes which, were it to reach the earth as pure water, it could not accomplish.

Composition of Rain-Water.—Numerous analyses of rain-water show that it contains in solution about 25 cubic centimetres of gases per litre. An average proportional percentage is by measure—nitrogen, 66.4; oxygen, 31.2; carbonic acid, 2.4,—the oxygen being in greater proportion than in air, owing to its greater solubility in water. Common salt, ammonia, sulphates, nitric acid, inorganic dust, and organic matter are usually present in minute quantities in rain water. So far as we know at present, the three ingredients which are chiefly effective in the chemical reactions due to rain are the oxygen, carbonic acid, and organic matter.¹

Permeability of all Rocks by Water.—Though minerals and rocks differ vastly in their degree of porosity, there is none known which is not in some degree permeable by water. Even such hard and apparently impenetrable substances as flint and agate are found to be permeable. For, in fact, rocks and minerals when examined with the microscope are seen to be made up of variously-shaped grains, crystals, or particles, and it is in the minute channels and interstices between these particles, or even through the particles themselves, that the water works its way. Evidently, the smaller the interstices the less easily will the water force a passage into or through the stone. This permeability, though well marked upon the surface of the land, becomes still more so underground, where the rocks are sometimes quite saturated with water.

Liability of all Rocks to alteration by Water.—There is probably no known substance which is not, under some condition, soluble in water containing carbonic acid or other natural reagent. Rain-water, descending with the gases, acids, and organic matter it has abstracted from the air and soil, effects a chemical disintegration of the rocks. This action was referred to in the description of the air as

¹ The organic matter is revealed by the putrid smell which long-kept rain water gives out. The reader who wishes to pursue this subject may consult the elaborate tables of analyses in Dr Angus Smith's *Air and Rain*. See also the section on air, *ante*, p. 220.

partly due to atmospheric moisture, but it is chiefly carried on by rain. And as rain is so widely and almost universally distributed over the globe, this chemical action must be of very general occurrences.

Nature of the Changes effected.—Confining our attention to its three chiefly active ingredients, we find that rain water reacts chemically upon rocks by—1. *Oxidation*.—The prominence of oxygen in rain-water, and its readiness to unite with any substance which can contain more of it, render this a marked feature of the passage of rain over rocks. A thin oxidized pellicle is formed on the surface, and thus, if not at once washed off by the rain, sinks deeper until a crust is formed over the stone. As already remarked, this process is simply a rusting of those minerals which, like metallic iron, have no oxygen, or have not their full complement of it. 2. *Decalcification*.—Organic matter having an affinity for more oxygen decomposes peroxides by depriving them of some part of their share of that element, and reducing them to protoxides. These changes are especially noticeable among the iron oxides so abundantly diffused among rocks. Hence rain-water, in sinking through soil and obtaining such organic matter, becomes thereby a reducing agent. 3. *Solution*.—This may take place either by the simple action of the water, as in the solution of rock-salt, or by the influence of the carbonic acid present in the rain. Of the latter (*Carbonation*) a familiar example is the corrosion of marble slabs down which rain has trickled for a time. The carbonic acid dissolves some of the lime, which as a bicarbonate is held in solution in the carbonated water, but is deposited again when the water loses its carbonic acid or evaporates. It is not merely carbonates, however, which are liable to this kind of destruction. Even silicates of lime, potash, and soda, combinations existing abundantly as constituents of rocks, are attacked; their silica is liberated, and their alkalies or alkaline earths, becoming carbonates, are removed in solution. 4. *Hydration*.—Some minerals, containing little or no water, and therefore called anhydrous, when exposed to the action of the atmosphere, absorb water, or become hydrous, and are then usually more prone to further change. Hence the rocks of which they form part become disintegrated.

Weathering.—The weathering of rocks is dependent upon two sets of conditions—(1) meteorological, as the range of temperature, abundance of moisture, height above the sea, and exposure, and (2) lithological,—the composition and texture of the rocks themselves. As regards the composition of rocks, those which consist of particles liable to little chemical change from the influence of moisture are best fitted to resist weathering, provided their particles have sufficient cohesion to withstand the mechanical processes of disintegration. Siliceous sandstones are excellent examples of this permanence. Consisting wholly or mainly of the durable mineral quartz, they are sometimes able so to withstand decay that buildings made of them still retain, after the lapse of centuries, the chisel-marks of the builders. Some rocks which yield with comparative rapidity to the chemical attacks of moisture show no marks of disintegration on their surface, which remains clean and fresh. This is particularly the case with limestones. The reason lies obviously in the fact that limestone when pure is wholly soluble in acidulous water. Rain falling on this rock removes some of it in solution, and will continue to do so until the rock is dissolved away. It is only where the limestone contains impurities that a weathered crust of more or less insoluble particles remains behind. Hence the relative purity of limestones may be roughly determined by comparing their weathered surfaces, where, if they contain much sand, the grains will be seen projecting from the calcareous matrix, and where should the

rock be very ferruginous, the yellow hydrous peroxide or ochre will be found as a powdery crust. In limestones containing abundant encrinurites, shells, or other organic remains, the weathered surface commonly presents the fossils standing out in relief. This seems to arise from the crystalline arrangement of the lime in the organic structures, whereby they are enabled to resist disintegration better than the general mechanically aggregated matrix of the rock. An experienced fossil collector will always search well those weathered surfaces, for he often finds there, delicately picked out by the weather, minute and frail fossils which are wholly invisible on a freshly broken surface of the stone. Many rocks weather with a thick crust or even decay inwards for many feet or yards. Basalt, for example, often shows a yellowish-brown ferruginous layer on its surface, formed by the conversion of its felspar into kaolin and the removal of its silicate of lime as carbonate, by the hydration of its olivine and augite and their conversion into serpentine, saponite, or some other hydrous magnesian silicate, and by the conversion of its magnetite into limonite. Granite sometimes shows in a most remarkable way the distance to which weathering can reach. It may often be dug into for a depth of 20 or 30 feet, the quartz crystals and veins retaining their original positions, while the felspar is completely kaolinized.

It is to the effects of weathering that the abundant fantastic shapes assumed by crags and other rocky masses are due. Most varieties of rock have their own characteristic modes of weathering, whereby they may be recognized even from a distance. To some of these features reference will be made in a subsequent section.

II. *MECHANICAL ACTION*.—When a rock has been so corroded by weathering that the cohesion of the particles on its exposed surface is destroyed, these particles are washed off by rain. This detritus is either held in suspension in the little runnels into which the rain-drops gather as they begin to flow over the land, or is pushed by them along the surface. In this way the rain causes off by mechanical movement what it has already loosened by chemical action.

III. *RESULTS OF RAIN-ACTION*.—It is evident that the general result of the fall of rain upon a land surface must be a disintegration and consequent lowering of that surface. At first we may be inclined to imagine that this waste must be so slow and slight as to be hardly appreciable. But a little observation will suffice to furnish many proofs of its existence and comparatively rapid progress in some places. We are familiar, for example, with the pitted channelled surface of the ground lying immediately under the drip of the eaves of a house. We know that the fragments of stone and gravel are left sticking up prominently because the earth around and above them has been washed away, and because, being hard, they resist the action of the falling drops and screen the earth below them. On a far larger scale we may notice the same kind of operation in districts of conglomerate, where the larger blocks, serving as a protection to the rock underneath, come to form as it were the capitals of slowly-deepening columns of rock. In the same way in certain valleys of the Alps a stony clay is cut by the rain into pillars, each of which is protected by, and indeed owes its existence to, a large block of stone which lay originally in the heart of the mass. These columns are of all heights, according to the positions in which the stones may have originally lain. There are instances, however, where the disintegration has been so complete that only a few scattered fragments remain of a once extensive stratum, and where it may not be easy to realize that these fragments are not transported boulders. In Dorsetshire and Wiltshire, for

example, the surface of the country is in some parts so thickly strewn with fragments of sandstone and conglomerate "that a person may almost leap from one stone to another without touching the ground. The stones are frequently of considerable size, many being four or five yards across, and about four feet thick."¹ They have been used for the huge blocks of which Stonehenge and other of the so-called druidical circles have been constructed, hence they have been termed Druid Stones. Other names are Sarsen Stones (supposed to indicate that their accumulation has been popularly ascribed to the Saracens), and Grey Wethers, from their resemblance in the distance to flocks of (wether) sheep. They are found lying abundantly on the chalk, suggestive at first of some former agent of transport by which they were brought from a distance. It is now, however, generally admitted that they are simply fragments of some of the sandy Tertiary strata which once covered the districts where they occur, and that while the softer portions of these strata have been carried away, the harder parts (their hardness perhaps increasing by exposure) have remained behind as Grey Wethers, and have subsequently suffered from the inevitable splitting and crumbling action of the weather.

But it is not from any single example, however striking, that the real importance of rain as a geological agent can be adequately realized. To form a true conception of this momentous action, we need to watch what takes place over a wide region. The whole land-surface over which rain falls is exposed to waste. As Hutton long ago insisted, the superficial covering of decayed rock or soil is constantly, though slowly, travelling outward and downward to the sea. In this ceaseless transport rain acts as the great carrying agent. The particles of rock loosened by atmospheric waste, by frost or the chemical disintegration of the rain itself, are washed off to form new soil. But they as well as the particles of the soil are step by step moved downward over the face of the land till they reach the nearest brook or river, whence their seaward progress may be rapid. A heavy rain discolours the water-courses of a country, because it loads them with the fine debris which it removes from the general surface of the land. In this way rain serves as the means whereby the work of the other disintegrating forces is made conducive to the general degradation of the land. The decomposed crust produced by weathering, which would otherwise accumulate over the solid rock and protect it from further decay, is removed by rain so as to expose a fresh surface to further decomposition. This decay is general and constant, but not uniform. In some places, from the nature of the rock, from the flatness of the ground, or from other causes, rain works under great difficulties. There the rate of waste must consequently be extremely slow. In other places, again, the rate may be rapid enough to be readily appreciable from year to year. A survey of this department of geological activity shows how the unequal wasting by rain has helped to produce the details of the present relief of the land, those tracts where the destruction has been greatest forming hollows and valleys, others, where it has been less, rising into ridges and hills.

Rain-action is not always merely destructive. Usually it is accompanied by reproductive effects, and, as already remarked, the mouldered rock which it washes off furnishes materials for the formation of soil. In favourable situations it has gathered together accumulations of loam and earth from neighbouring higher ground—the "brick-earth," "head," and "rain-wash" of the south of England—earthy

deposits, sometimes full of angular stones, derived from the subaerial waste of the rocks of the neighbourhood.²

§ 2. *Underground Water.*

When rain falls upon the land its further progress becomes twofold. The greater part of it sinks into the ground and apparently disappears, the rest flows off into runnels, brooks, and rivers, and in this way moves downward to the sea. It is most convenient to follow first the course of the subterranean water.

We have seen that all rocks are more or less porous. They are moreover traversed by abundant joints and cracks. Hence, from the bed of the ocean, from the bottoms of lakes and rivers, as well as from the surface of the land on which rain falls, water is continually filtering downward into the rocks beneath. To what depth this descent of the surface water may go is not known. It may reach as far as the intensely heated interior of the planet, for, as the researches of M. Daubrée have shown, capillary water has the capacity of penetrating rocks even against a high counter-pressure of vapour. The water at extreme depths may be under such pressure as to retain its liquid condition at a red or even at a white heat. Probably the depth to which the water descends varies indefinitely according to the varying nature of the rocky crust. Some shallow mines are practically quite dry, while others of great depth require large pumping engines to keep them from being flooded by the water which pours into them from the surrounding rocks. As a rule, however, the upper layers of rock are fuller of moisture than those deeper down.

The water which in this way sinks into the earth is not permanently removed from the surface, though there may perhaps be a slight loss due to absorption and chemical alteration of the rocks. It accumulates underneath, until by the pressure of the descending column it is forced to find a passage through joints or fissures upward to the surface. The points at which it issues are termed *springs*. In most districts the rocks underneath are permeated with water below a certain limit which is termed the *water-level*. This line is not a strictly horizontal one like that of the surface of a lake. Moreover, it is liable to rise and fall according as the seasons are wet or dry. In some places it lies quite near, in others far below, the surface. A well is an artificial hole dug down below the water-level, into which the water percolates. Hence, when the water-level happens to be at a small depth the wells are shallow, when at a great depth they require to be deep.

Since the rocks underneath the surface vary greatly in porosity, some contain far more water than others. It often happens that, percolating along some porous bed, the subterranean water finds its way downward until it passes under some more impervious rock. Hindered in its progress, it accumulates in the porous bed, from which it may be able to find its way up to the surface again only by a tedious circuitous passage. If, however, a bore-hole be sunk through the upper impervious bed down to the water-charged stratum below, the water will eagerly avail itself of this artificial channel of escape, and will rise in the hole, or even rush up and gush out as a *jet d'eau* above ground. Wells of this kind are now largely employed. They bear the name of *Artesian*, from the old province of Artois in France, where they have long been in use.

That the water really circulates underground, and passes

¹ See Austen, *Quart. Journ. Geol. Soc.*, vi 94, vii 121; Foster and Topley, *Quart. Journ. Geol. Soc.*, xxi 446.

² This term *impervious* must evidently be used in a relative and not in an absolute sense. A stiff clay is practically impervious to the trickle of underground water; hence its employment as a material for puddling (that is, making water-tight) canals and reservoirs. But it contains abundant interstitial water, on which indeed its characteristic plasticity depends.

¹ See *Descriptive Catalogue of Rock Specimens in Jermyn Street Museum*, 3d ed., Prestwich, *Quart. Journ. Geol. Soc.*, x p 123; Whitaker, *Geological Survey Memoir on parts of Middlesex, &c.*, p. 71.

not merely between the pores of the rocks but in crevices and tunnels which it has no doubt to a large extent opened for itself along numerous natural joints and fissures, is proved by the occasional rise of leaves, twigs, and even live fish, in the shaft of an Artesian well. Such evidences are particularly striking when found in districts without surface waters, and even perhaps with little or no rain. They have been met with, for instance, in sinking wells in some of the sandy deserts on the southern borders of Algeria. In these and similar cases it is clear that the water may, and sometimes does, travel for many leagues underground away from the district where it fell as rain or snow, or where it leaked from the bed of a river or lake.

The temperature of springs affords a convenient but not always quite reliable indication of the relative depth from which they have risen. Some springs are just one degree or less above the temperature of ice. Others in volcanic districts issue with the temperature of boiling water. Between these two extremes every degree may be registered. Very cold springs may be regarded as probably deriving their supply from cold or even snow-covered mountains. Certain exceptional cases, however, occur where ice forms in caverns (*glacières*) even in warm and comparatively low districts. Water issuing from these ice caves is of course cold.¹ On the other hand, springs whose temperature is much higher than the mean temperature of the places at which they emerge must have descended far enough to be warmed by the internal heat of the earth. The hottest springs are found in volcanic districts. But even at a great distance from any active volcano, *thermal springs*, as they are called, appear with a temperature of 120° Fahr. (which is that of the Bath springs) or even more. These have probably risen from a great depth. If we could assume a progressive increase of 1° Fahr. of subterranean heat for every 60 feet of descent, the water at 120° issuing at a locality whose ordinary temperature is 50°, should have been down at least 4200 feet below the surface. But from what has been stated in a previous section (p. 224) regarding the irregular stratification of temperature within the earth's crust, such estimates of the probable depth of the sources of springs are liable to various errors.

Apart from its vast importance in a social point of view, the underground circulation of water has a profound interest for the geologist, from the light which it affords as to the changes that rocks undergo, and the manner in which these changes are effected. For, like all the other geological agents, it does not move on its course without doing work. We have now to inquire what is the nature of that work. A convenient arrangement will be to group its study under two heads—(1) chemical action, and (2) mechanical action.

(1.) Every spring, even the most clear and sparkling, contains mineral matter in chemical solution, obtained from the rocks through which the water travels in its journey from the surface into the interior, and back to the surface again. The nature of the mineral ingredients depends partly upon the composition of the rocks traversed, partly upon the gases, acids, or other reagents which may have been present in the rain, or may have been obtained by the water in its subterranean journey, and partly upon the depth to which the water may have reached and the temperature to which it may have been raised.

We have already (*ante*, p. 267) considered the substances extracted by rain from the air and used by it in the disintegration of rocks. The same reagents are of course carried

underneath the ground, when the rain-water sinks out of sight, and continue there the processes of decomposition and alteration which they are seen to effect at the surface. But other sources are open to the subterranean water for the augmentation of its chemical reagents. (1.) In descending through the soil the meteoric water encounters abundant organic matter, which abstracts its oxygen and replaces it by carbonic acid. This interchange probably in many cases far more than compensates for the expenditure of these gases employed in subaerial disintegration. In so far as the water carries down from the soil any oxidizable organic substance, its action must be to reduce the oxides it encounters among rocks. It is remarkable that ordinary vegetable soil possesses the power of removing from the water which permeates it potash, silica, phosphoric acid, ammonia, and organic matter, elements which had been already in great measure abstracted from it by living vegetation, and which are again taken up by the same organic agents. (2.) Carbonic acid gas is sometimes largely evolved within the earth's crust, especially in regions of extinct or dormant volcanoes. Subterranean water coming in the way of this gas greedily dissolves it, and thereby obtains an enormously increased power of attacking even the most obdurate rocks. (3.) Whenever the water has its temperature considerably raised, its solvent capacity, especially for silica, is largely augmented. Hot springs often contain a large proportion of that substance in solution. (4.) The production of some of the compounds which are due to decompositions effected by the water, and are carried along with it in solution, increases its ability to accomplish further decompositions. Thus the alkaline carbonates, which are among the earliest products of the action of the water, enable it to dissolve silica and decompose silicates.

The study of these alterations belongs to the subject of Metamorphism, of which some account has already been given (*ante*, p. 262). Let us look at the results achieved by them, as shown in the composition of the water which issues from different springs. Considered from this point of view, springs may be treated as (1) common or ordinary springs, that is, those which contain only such average proportions of mineral matter as occur in ordinary potable water, and (2) mineral springs, or those where the proportion of foreign ingredients is large enough to give a marked character to the water. These two groups, however, merge insensibly into each other.

Common Springs.—The materials ordinarily present in common spring water are, besides atmospheric air and its gases, carbonate and sulphate of lime, common salt, with chlorides of calcium and magnesium, and sometimes organic matter. The amount of dissolved contents in ordinary drinking water does not exceed 5 or at most 1.0 gramme per litre; the best waters contain even less.

Mineral Springs.—These may be roughly but conveniently classified according to the prevailing mineral substance contained in them, which may range in amount from 1 to 300 grammes per litre.²

Calcareous—containing so much lime that it is deposited as a white crust as the water evaporates. Spring water when saturated with carbonate of lime contains about 105 parts in 100,000. Springs of this kind are common in limestone countries. As the water flows away from its point of exit, it throws down a deposit of calcareous tufa or travertine, which, as it encrusts moss, twigs, and other objects, gives them the appearance of having been turned into stone, whence the springs are popularly termed "petrifying." Enormous accumulations of this kind have been formed in some parts of Italy, where the rock so produced is extensively quarried as a building material.

Ferruginous or Chalybeate—containing a large proportion of iron in the total mineral ingredients. Such waters have an inkly taste, and often deposit along their course a yellow, brown, or red ochry

¹ The most remarkable example of a *glacière* yet observed is that of Dobosban, in Hungary, of which an account, with a series of interesting drawings, was published in 1874 by Dr J. A. Krenner, keeper of the national museum in Buda-Pesth.

² Paul, in Watt's *Chem. Diet.*, v., 1016.

deposit, consisting mainly of hydrated peroxide of iron. They may be frequently observed in those districts where beds of veins of nonstone occur, or where the rocks contain much iron in combination.

Siliceous—depositing silica or flint. Although silica may be dissolved and retained in solution even in cold water, it is in the hot water issuing in volcanic countries that it occurs most abundantly, and where true siliceous springs exist. The geysers of Iceland, New Zealand, the Yellowstone region, and other districts are illustrations. When the heated water of these thermal springs cools and evaporates, the silica is deposited as siliceous sinter round their basins, or in picturesque mounds at the point of escape. One of the sinter beds in the geyser region of Iceland is said to be two leagues long, a quarter of a league wide, and a hundred feet thick. As already stated (*note*, p 263), the effect of pressure is to enable water at great depths to retain a larger amount of mineral matter in solution. Hence, when the water ascends, it deposits its mineral contents, not only because it cools, but because the pressure is removed. There must in many cases be a copious deposit along the walls of the fissures up which the water flows on its way to the surface. Doubtless in this way many mineral veins have received their successive coatings of quartz, Jasper, gypsum, calcite, and other minerals.

Brine—bringing to the surface a solution, more or less nearly saturated, of chloride of sodium. Springs of this kind appear where beds of solid rock-salt exist underneath. The water in its passage encounters the salt, dissolves it, and brings it to the surface. The brine springs of Cheshire in England, the Salzkammergut in Austria, Bex in Switzerland, &c, have long been well known. Some of the English brines contain about one per cent of salts, of which the chloride of sodium may range from a half to three-fourths or more. Other brines, however, yield a far larger amount; one at Clemensthal, Wittenburg, gave upwards of 26 per cent of salts, of which almost the whole was chloride of sodium. The other substances contained in solution in the water of brine springs are usually such as exist also in sea-water, such as sulphate and carbonate of lime, chlorides of magnesium and potassium, &c.

Medicinal—a vague term applied to mineral springs which have or are believed to have curative effects in different diseases. Medical men recognize various qualities, distinguished by the particular substance most conspicuous in each—such as *Alkaline Waters*, containing lime or soda and carbonic acid, as those of Vichy or Saratoga; *Bitter Waters*, with sulphates of magnesium and soda; Seelitz, Kissingen; *Salt or Mineral Waters*, with common salt as the leading mineral constituent—Wiesbaden, Cheltenham; *Berthol Waters*, lime, either a sulphate or carbonate, being the most marked ingredient—Bath, Lucca; *Sulphurous Waters*, with sulphur as sulphuretted hydrogen and in sulphides—Aix-la-Chapelle, Harrogate.

Oil—Mineral oil is carried up by some ordinary springs, and floats in dark drops on the surface of the water. But in some parts of the world, as in a wide region in the Northern States of the American Union and in Canada, the oil ascends with little or no water, and forms the oil-springs which in recent years have become so remarkable and abundant a source of illuminating oils, paraffin, and other hydrocarbon compounds.

Results of Chemical Action of Underground Water.—Since every spring is busily engaged in bringing mineral substances from below ground to the surface, there must evidently be a vast amount of subterranean waste, and many tunnels, channels, and caverns must in consequence be formed. To take one illustration: the warm springs of Bath, with a mean temperature of 120° Fahr, are impregnated with sulphates of lime and soda, and chlorides of sodium and magnesium. Professor Ramsay has estimated their annual discharge of mineral matter to be equal to a square column 9 feet in diameter and 140 feet in height. It is in calcareous regions that the extent of the subterranean loss can be most strikingly seen. Sometimes a district of limestone is drilled with vertical cavities (*sulphotubes* or *sinks*) formed by the solution of the rock by the descent of carbonated rain-water. Surface-drainage is there intercepted, and passes at once under ground, where, in course of time, an elaborate system of channels may be dissolved out of the solid rock. Such has been the origin of the Peak caverns of Derbyshire, the intricate grottoes of Antiparos and Adelsberg, and the vast labyrinths of the Mammoth Cave of Kentucky. In the course of time the underground rivers open out new courses, and leave their old ones dry. By the falling in of the roofs of caverns near the surface, brooks and rivers are occasionally en-

gulfed, which, after a long subterranean course, may issue to the surface again in a totally different surface area of drainage to that in which they took their rise, and sometimes, as in Florida, with volume enough to be navigable almost up to their outflow. In such circumstances lakes may be formed over the sites of the broken-in caverns; and valleys may thus be deepened, or perhaps even formed. Mud, sand, and gravel, with the remains of plants and animals, are swept below ground, and sometimes accumulate in deposits there. This has been the origin of ossiferous caverns, and of the loam and breccia so often found in them.

These wonderful results of the subterranean circulation of water appeal to the imagination, and are those usually most dwelt upon as evincing the potency of this kind of geological agency. And yet the thoughtful observer who reflects upon this subject will perhaps be led to perceive that even more important than these visible caverns and grottoes are the silent unobtrusive changes so constantly in progress in the solid heat of rocks. As far down as percolating water reaches there is not a particle of mineral matter safe from its attacks. And as we have seen, it is hardly possible to find any rock which does not bear throughout its minute grains and pores evidence that water has filtered through it, removing some substances and putting others in their place.

(2) *Results of Mechanical Action.*—In its passage along fissures and channels of the rocks, the underground water not merely dissolves materials chemically and removes them in solution, it likewise loosens some of the finer particles from the sides of these subterranean conduits and carries them along in mechanical suspension. We may occasionally observe, where a spring gushes forth at the surface, that grains of sand are brought up in the clear sparkling water. This removal of material sometimes produces remarkable surface changes when it takes place along the side of a steep slope or cliff, such as occur in river valleys, or by the sea-coast. Let us suppose a thin layer of some porous material, like loose sand or ill-compacted sandstone to lie between two more impervious rocks such as masses of clay or limestone, and that this porous stratum sloping down from higher ground comes out to the surface near the base of a line of abrupt cliff. The water which finds its way down into this layer will use it as its channel of escape, and travelling along its course will issue in springs or in a more general oozing forth along its outcrop at the foot of the declivity. Under these circumstances the support of the overlying mass of rock is apt to be loosened. The water not only removes piece-meal the sandy layer on which that overlying mass rests, but as it were lubricates the rock underneath. Consequently at intervals portions of the upper rock may break off and slide down into the valley or plain below. Such dislocations are known as *landslips*. Many illustrative examples might be cited. Thus in the year 1839 a mass of chalk on the Dorsetshire coast slipped over a bed of clay into the sea, leaving a rent three-quarters of a mile long, 150 feet deep, and 240 feet wide. The shifted mass, bearing with it houses, roads, and fields, was cracked, broken, and tilted in various directions, and was thus prepared for further attack and removal by the waves. On many parts of the coasts of Britain there are landlips on a large scale which doubtless took place many centuries ago, or even in some cases beyond the times of human history. The undercliff of the Isle of Wight, the cliffs west of Brandon Head, county Kerry, the basalt escarpments of Antrim, and the edges of the great volcanic plateaus of Mull, Skye, and Raasay furnish illustrations of such prehistoric landlips. Of Continental examples, the well-known fall of the Rossberg, behind the Righi in Switzerland, is one of the most memorable. After a rainy summer in 1806 a large

part of one side of the mountain, consisting of sloping beds of hard red sandstone and conglomerate, resting upon soft sandy layers, gave way. Thousands of tons of solid rock suddenly swept across the valley of Goldau, burying four villages, with about 500 of their inhabitants. In 1855 a mass of debris, 3500 feet long, 1000 feet wide, and 600 feet high, slid into the valley of the Tiber, which, dammed back by the obstruction, overflowed the village of San Stefano to a depth of 50 feet, until drained off by a tunnel.

§ 3. Brooks and Rivers.

These will be considered under four aspects:—(1) their sources of supply, (2) their discharge, (3) their flow, and (4) their geological action.

I. SOURCES OF SUPPLY.—Rivers are the natural drains of a land surface. They carry out to sea the surplus water after evaporation, and not water only, but a vast and almost incredible amount of material annually worn off the land. Their contents are derived partly from rain (including mist and dew) and melted snow, partly from springs. In a vast river system like that of the Mississippi, the area of drainage is so extensive as to embrace many different climates and varieties of rainfall, so that on the whole the amount of discharge, being in a great measure independent of local variations in the weather, remains tolerably uniform. But in smaller rivers, such as those of Britain, whose basins lie in a region having the same general features of climate, the quantity of water is regulated by the local rainfall. A wet season swells the streams, a dry one diminishes them. Were rivers entirely dependent, however, upon direct supplies of rain, they would only flow in rainy seasons, and disappear in dry weather. This does not happen, because they derive a great deal of their water not directly from rain, but indirectly through the intermediate agency of springs. Hence they continue to flow even in very dry weather, because, though the superficial supplies have failed, the underground sources still continue available. In a long drought, however, the latter begin to fail, the surface springs ceasing first, and gradually drying up in their order of depth, until at last only deep-seated springs furnish a perhaps daily diminishing quantity of water. It is a matter of great economic as well as scientific interest to know how long any river would continue to yield a certain amount of water during a prolonged drought. So far as we can tell, no rule could possibly be laid down for a generally applicable calculation, every area having its own peculiarities of underground drainage. Mr Joseph Lucas gives some particulars which show what may happen in a chalk district. The river Wandle drains an area of 51 square miles of the chalk downs in the south-east of England. For eighteen months, from May 1858 to October 1859, as tested by gauging, there was very little absorption of rainfall over the drainage basin, and yet the minimum recorded flow of the Wandle was 10,000,000 gallons a-day, which, Mr Lucas says, represents not more than 4090 inch of rain absorbed on the 51 square miles of chalk. The rock is so saturated that it can continue to supply a large yield of water for eighteen months after it has ceased to receive supplies from the surface, or at least has received only very much diminished supplies.¹

II. DISCHARGE.—As the natural drains of the land, rivers carry the surplus moisture out to sea. What proportion of the total rainfall is thus discharged by them is a question of great geological and industrial interest. From the very moment that water takes visible form as mist, cloud, dew, rain, snow, or hail, it is subject to evaporation. When it reaches the ground, or flows off into brooks, rivers, lakes, or

the sea, it undergoes continual diminution from this cause. Hence in regions where rivers receive no tributaries, they grow smaller in volume as they move onward, till they sometimes even disappear. Apart from temperature, the amount of evaporation is very largely regulated by the nature of the surface from which it takes place, one soil or rock differing from another, and all of them probably from a surface of water. There is no question in meteorology where full and detailed observations are more wanting than in the determination of the relation of evaporation to rainfall and river discharge.² During severe storms of rain, the water discharged over the land of course to a very large extent finds its way at once into brooks and rivers, where it causes floods, and whence it reaches the sea. Mr David Stevenson remarks that, according to different observations, the amount carried off in floods varies from 1 to 100 cubic feet per minute per acre.³ But though floods cannot be deemed exceptional phenomena, forming as they do a part of the regular system of water circulation over the land, they do not represent the ordinary proportions between rainfall and river discharge in such a climate as that of Britain, where the rainfall is not crowded into one season, but is spread more or less equally throughout the year. According to Beardmore's table,⁴ the Thames at Staines has a mean annual discharge of 32 40 cubic inches per minute per square mile, equal to a depth of 7 31 inches of rainfall run off, or less than a third of the total rainfall. The most carefully collected data at present available are probably those given by Humphreys and Abbot for the basin of the Mississippi and its tributaries as shown in the subjoined table:—

	Ratio of Discharge to Rainfall
Ohio River	0 24
Missouri River	0 15
Upper Mississippi River	0 24
Small tributaries	0 90
Arkansas and White River	0 15
Red River	0 20
Yazoo River	0 90
St Francis River	0 90
Entire Mississippi, exclusive of Red River	0 25

Perhaps in Great Britain not more than a fourth part of the total moisture deposited on the land from the atmosphere is carried out to sea by streams.⁵ But this is a point on which, until far more facts have been gathered, no definite statement can be accepted as at all trustworthy.

III. FLOW.—Rivers, in obedience to the law of gravitation, always move from a higher to a lower level. Where the channel of a river becomes vertical, or nearly so, a water

¹ In the present state of our information it seems almost useless to state any of the results already obtained, so widely discrepant and inconceivable are they. In some cases the evaporation is given as usually three times the rainfall; and that the evaporation always exceeded the rainfall was for many years the belief among the French hydraulic engineers. (See *Annales des Ponts et Chaussées*, 1850, p. 383.) Observations on a larger scale, and with greater precautions against the undue heating of the evaporator, have since shown, as might have been anticipated, that as a rule, save in exceptionally dry years, the evaporation is lower than the rainfall. As the average of ten years from 1860 to 1869 Mr Gieseler found that at Lea Bridge the evaporation from a surface of water was 20 946, while the rainfall was 25 534 (Symon's *British Rainfall* for 1869, p. 162). But we need a vast accumulation of observations, taken in many different situations and exposures, in different rocks and soils, and at various heights above the sea. (For a notice of a method of trying the evaporation from soil, see *British Rainfall*, 1872, p. 206.)

² *Reclamation and Protection of Agricultural Land*, Edin., 1871, p. 15.

³ *Hydrology*, p. 201.

⁵ In mountainous tracts having a large rainfall and a short descent to the sea, the proportion of water returned to the sea must be very much greater than this. Mr Bateman's observations for seven years in the Loch Katine district gave a mean annual rainfall of 87½ inches at the head of the lake, with an outflow equivalent to a depth of 81·70 inches of rain removed from the drainage basin of 71½ square miles.

¹ Lucas, *Horizontal Wells*, London, 1874, pp. 40, 41. See also Benthwaite, "On the Rise and Fall of the Wandle," *Minutes Proc. Inst. C.E.*, xx.

fall is formed ; a steep rocky declivity in the channel gives rise to rapids , a flat plain allows the stream to linger with a scarcely perceptible current , while a lake renders the flow nearly or altogether imperceptible. Thus the rate of flow is regulated in the main by the angle of inclination and form of the channel, but partly also by the volume of water, an increase of volume in a narrow channel increasing the rate of motion even without an increase of slope.

The course of a great river may be divided into three parts — 1. *The Mountain Track*,—where, amidst the clouds and snows it takes its rise as a mere brook, and, fed by innumerable similar torrents, dashes rapidly down the steep sides of the mountains, leaping from crag to crag in endless cascades, growing every moment in volume, until it enters lower ground. 2. *The Valley Track*.—It now flows through the lower hills or undulations which traverse or flank a great mountain chain, and is found at one time in a wide fertile valley, then in a dark gorge, now falling headlong in a cataract, now expanding into a broad lake. This is the part of its career where it assumes the most varied aspects, receives the largest tributaries, and fulfils most characteristically the various conditions which are present to our minds in the idea of a river. 3. *The Plain Track*.—Having quitted the undulating region, it finally emerges upon broad plains, probably wholly, or in great part, made by itself. Here it winds sluggishly in wide curves, perhaps divides so as to enclose tracts of flat meadow or marsh, and finally, amid banks of mud and sand, passes out into the great ocean. In Europe the Rhine, Rhone, and Danube, in Asia the Ganges and Indus, in America the Mississippi and Amazon, in Africa the Nile, more or less fully illustrate this typical course of a great river.

If we draw a longitudinal section of the course of any such river from its source, or from the highest peaks around that source to its mouth at the sea, we find that the line forms a concave curve. Step at first, where it slopes from the mountain crests down into the valleys, the curve grows less and less through the middle portion, until it finally can hardly be distinguished from a horizontal line. Though characteristic of great rivers, this feature is not confined to their courses, but belongs to the architecture of the continents.

It is evident that a river must flow, on the whole, fastest in the first portion of its course, and slowest in the last. The common method of comparing the fall or slope of rivers is to divide the difference of height between their source and the sea-level by their length, so as to give the declivity per mile. This mode, however, often fails to bring out the real resemblances and differences of rivers, even in regard to their angle of slope. For example, two streams rising at a height of 1000 feet, and flowing 100 miles, would each have an average slope of 10 feet per mile ; yet they might be wholly unlike each other, one making its descent almost entirely in the first or mountain part of its course, and lazily winding for most of its way through a vast low plain, the other toiling through the mountains, then keeping among hills and table-lands, so as to form on the whole a tolerably equable and rapid flow. The great rivers of the globe have probably a less average slope than 2 feet per mile. The Missouri has a descent of 28 inches per mile. The average slope of the channel of the Thames is 21 inches per mile, of the Shannon about 11 inches per mile, but between Killaloe and Limerick about $6\frac{1}{2}$ feet per mile ; of the Nile, below Cairo, 3.25 to 5.5 inches per mile ; of the Doubs and Rhone, from Besançon to the Mediterranean, 24.18 inches per mile ; of the Volga, from its source to the sea, a little more than 3 inches per mile. Higher angles of descent are those of torrents, as the Arve, with a slope of 1 in 616 at Chamounix, and the Durance, whose angle varies from 1 in 467 to 1 in 208. The slope of a navigable river

ought not, if possible, to exceed 10 inches per mile, or 1 in 6336.¹

But not only does the rate of flow of a river vary at different parts of its course, it is not the same in every part of the cross section of the river taken at any given point. The sides and bottom, being retarded by friction against the channel, move less rapidly than the centre. The central piers of a bridge have thus a greater velocity of river current to bear than those at the banks. It follows that whatever tends to diminish the friction of the moving current will increase its rate of flow. The same body of water, other conditions being equal, will move faster through a narrow gorge with steep smooth walls than over a broad rough rocky bed. For the same reason, when two streams join, their united current, having in many cases a channel not much larger than that of one of the single streams, flows faster, because the water encounters now the friction of only one channel. The average rate of flow of rivers is much less than might be supposed, even in what are termed swift rivers. A moderate rate is about $1\frac{1}{2}$ mile in the hour, even that of a torrent does not exceed 18 or 20 miles in the hour.² Mr D. Stevenson states that the velocity of such rivers as the Thames, the Tay, or the Clyde may be found to vary from about one mile per hour as a minimum to about three miles per hour as a maximum velocity.³

It may be remarked, in concluding this part of the subject, that elevations and depressions of the land must have a powerful influence upon the slope of rivers. The upraising of the axis of a country must increase the slope, and consequently the rate of flow which, on the contrary, will be diminished by a depression of the axis or by an elevation of the maritime regions.

IV. GEOLOGICAL ACTION.—Like all the other forms of moving water, the streams which traverse a country have both a *chemical* and *mechanical* action. The latter receives most attention, as it undoubtedly is the more important ; but the former ought not to be omitted in any survey of the general waste of the earth's surface.

i. *Chemical*.—The water of rivers must possess the powers of a chemical solvent like rain and springs, though its actual work in this respect can be less easily measured, seeing that river water is directly derived from rain and springs, and necessarily contains in solution mineral substances supplied to it by them and not by its own operation. Nevertheless, it is sometimes easy to prove that streams dissolve chemically the rocks of their channels. Thus in limestone districts the base of the cliffs of river ravines may be found eaten away into tunnels, arches, and overhanging projections, presenting in their smooth surfaces a great contrast to the angular jointed faces of the same rock where exposed to the influence only of the weather on the higher parts of the cliff.

The composition of the river waters of western Europe is well shown by numerous analyses. The substances held in solution include variable proportions of the carbonates of lime, magnesia, and soda ; silica ; peroxides of iron and manganese ; alumina ; sulphates of lime, magnesia, potash, and soda ; chlorides of sodium, potassium, calcium, and magnesium ; silicate of potash, nitrates ; and organic matter. The minimum proportion of mineral matter among the analyses collected by Bischof was 2.61 in 100,000 parts of water in a mountain stream 3800 feet above the sea. On the other hand as much as 54.5 parts in the 100,000 were obtained in the waters of the Beuvronne, a tributary of the Loire above Tours. The average of the whole of these analyses is about 21 parts of mineral matter in 100,000 of water, whereof carbonate of lime usually forms the half, its mean quantity

¹ D Stevenson, *Canal and River Engineering* p. 224.

² Conjean, *Géologie*, p. 225.

³ *Reclamation of Land*, p. 18.

being 11.34. Bischof calculated that, assuming the mean quantity of carbonate of lime in the Rhine to be 9.46 in 100,000 of water, which is the proportion ascertained at Bonn, enough carbonate of lime is carried into the sea by this river for the annual formation of three hundred and thirty-two thousand millions of oyster shells of the usual size. The mineral next in abundance is sulphate of lime, which in some rivers constitutes nearly half of the dissolved mineral matter. Silica amounting to 4.88 parts in 100,000 of water has been found in the Rhine, near Strasburg. The largest amount of alumina was 0.71 in the Loire, near Orleans. The proportion of mineral matter in the Thames, near London, amounts to about 33 in 100,000 parts of water, 15 of which (nearly half of the whole) consist of carbonate of lime.

It requires some reflection properly to appreciate the amount of solid mineral matter which is every year carried in solution from the rocks of the land and diffused by rivers into the sea. According to recent calculations by Mr T. Mellard Reade, C.E., a total of 8,370,630 tons of solids in solution is every year removed by running water from the rocks of England and Wales, which is equivalent to a general lowering of the surface of the country from that cause alone at the rate of .0077 of a foot in a century or one foot in 12,978 years. The same writer computes the annual discharge of solids in solution by the Rhine to be equal to 92.3 tons per square mile, that of the Rhone at Avignon 232 tons per square mile, and that of the Danube at 72.7 tons per square mile; and he supposes that on an average over the whole world there may be every year dissolved by rain about 100 tons rocky matter per English square mile of surface.¹

ii. *Mechanical*.—The mechanical work of rivers is threefold:—(1) to transport mud, sand, gravel, or blocks of stone from higher to lower levels; (2) to use these loose materials in eroding their channels; and (3) to deposit these materials where possible, and thus to make new geological formations.

1 Transporting Power.—It is one of the distinctions of river water, as compared with that of springs, that, as a rule, it is less transparent, that is, it contains more or less mineral matter in suspension. The same stream differs much at successive intervals in the amount of material thus transported. In dry weather when the water is low it may be tolerably clear; but a sudden heavy shower or a season of wet weather will render it turbid. The mud thus so frequently noticeable in rivers is partly derived from the surface of the ground on either side, whence it is washed into the main streams by rain and brooks, but partly also by the abrasion of the water-channels through the operations of the streams themselves. In the mountain tributaries of a river we find the channels choked with large fragments of rock disengaged from the cliffs and crags on either side. Traced downwards the blocks are seen to become gradually smaller and more rounded. They are ground against each other and upon the rocky sides and bottom of the channel, getting more and more reduced as they descend, and at the same time abrading the rocks over or against which they are driven. Hence a great deal of debris is produced, and is swept along by the onward and downward movement of the brooks and rivers. The finer portions, such as mud and fine sand, are carried in suspension, and impart the characteristic turbidity to rivers; the coarser sand and gravel are driven along the river bottom.

The transporting capacity of a stream depends (a) on the the volume and velocity of the current, and (b) on the size, shape, and specific gravity of the sediment. (a) According to the calculations of Hopkins, the capacity of transport

increases as the sixth power of the velocity of the current; thus the motive power of the current is increased 64 times by the doubling of the velocity, 729 times by trebling, and 4096 times by quadrupling it. It has been found by experiment that "ordinary sandy soil is moved by a current having a velocity of about half a mile an hour, and that a current of about one mile per hour will move fine gravel, while heavy gravel resists a current of upwards of two miles per hour." Mr David Stevenson² gives the subjoined table of the power of transport of different velocities of river currents.

In feet	Mile per Second	per Hour
8	= 0 170	will just begin to work on fine clay
6	= 0 340	will lift fine sand
8	= 0 4545	will lift sand as coarse as lunseed
12	= 0 6819	will sweep along fine gravel
24	= 1 3638	will roll along rounded pebbles 1 inch in diameter.
36	= 2 045	will sweep along shelly angular stones of the size of an egg

We must never lose sight, however, of the fact that it is not the surface velocity, nor even the mean velocity, of a river which can be taken as the measure of its power of transport, but the bottom velocity—that is, the rate at which the stream overcomes the friction of its channel. (b) The average specific gravity of the stones in a river ranges between two and three times that of pure fresh water, hence these stones lose from a half to a third of their weight in air when borne along by the river. Huge blocks which could not be moved by the same amount of energy applied to them on dry ground are swept along with ease when they have found their way into a strong river current. The shape of the fragments greatly affects their portability, when they are too large and heavy to be carried in mechanical suspension. Rounded stones are of course most easily moved; flat and angular ones are moved with comparative difficulty.

Besides their ordinary powers of transport, rivers gain at times considerable additional force from several causes. Those liable to sudden and heavy falls of rain acquire by flooding an enormous increase of transporting and excavating power. More work may thus be done by a stream in a day than could be accomplished by it during years of its ordinary condition.³ Another source of increase to the action of rivers is provided when, from landslips, formed by earthquakes, by the undermining influence of springs, or otherwise, a stream is temporarily dammed back, and the barrier subsequently gives way. The bursting out of the arrested waters produces great destruction in the valley. Blocks as big as houses may be set in motion, and carried down for considerable distances. Again, the transporting power of rivers is greatly augmented in countries where they freeze in winter. As the ice gathers along the banks it encloses gravel, sand, and even large blocks of rock, which, when thaw comes, are lifted up by the ice and carried down the stream. Ground-ice likewise appears in cold latitudes on the bottoms of the rivers, whence, rising in cakes to the surface, it carries with it sand, mud, or stones lying on the bottom, which are then swept seaward. When rivers such as those of northern Russia and Siberia, flowing from south to north, have the ice thawed in their higher courses before it breaks up farther down, much disaster is sometimes caused by the piling up of the ice, and then by the bursting of the impeded river through the temporary ice-barrier. In another way ice sometimes vastly increases the destructive

² *Canal and River Engineering*, p. 315.

³ The extent to which heavy rains can alter the usual characters of rivers is forcibly exemplified in the graphic account of *The Morayshire Floods*, by the late Sir T. Dick Lauder. In the year 1829 the rivers of that region rose 10, 18, and in one case even 50 feet above their common summer level, producing almost incredible havoc.

¹ Address to Liverpool Geological Society, 1877

powers of small streams where avalanches or an advancing glacier cross a valley and pond back its drainage. The valley of the Drance, in Switzerland, has several times suffered from this cause. In 1818 the glacier barrier extended across the valley for more than half a mile, with a breadth of 600 and a height of 400 feet. The waters above the ice-dam accumulated into a lake containing 800,000,000 cubic feet. By a tunnel driven through the ice, the river was drawn off without desolating the plains below.

That rivers differ vastly from each other in the amount of material they transport is made evident by the great diversities in their relative muddiness. It should be borne in mind that the actual amount of sediment borne downwards by a river is not necessarily determined by the carrying power of the current. The swiftest streams are not always the muddiest. The proportion of sediment is partly dependent upon the hardness or softness of the rocks of the channel, the number of tributaries, the nature and slope of the ground forming the drainage basin, the amount and distribution of the rainfall, the size of the glaciers (where such exist) at the sources of the river, &c. A rainfall spread with some uniformity throughout the year may not sensibly darken the rivers with mud, but the same amount of fall crowded into a few weeks or months may be the means of sweeping a vast amount of earth into the rivers, and sending them down in a greatly discoloured state to the sea. Thus the rivers of India during the rainy season become rolling currents of mud.

In his journeys through equatorial Africa Livingstone came upon rivers which appear usually to consist more of sand than of water. He describes the Zingesi as "a sand rivulet in flood, 60 or 70 yards wide, and waist-deep. Like all these sand-rivers it is for the most part dry; but, by digging down a few feet, water is to be found, which is percolating along the bed on a stratum of clay. In trying to ford it," he remarks, "I felt thousands of particles of coarse sand striking my legs, which gave me the idea that the amount of material removed by every freshet must be very great. . . . These sand rivers remove vast masses of disintegrated rock before it is fine enough to form soil. In most rivers where much wearing is going on, a person diving to the bottom may hear literally thousands of stones knocking against each other. This attrition, being carried on for hundreds of miles in different rivers, must have an effect greater than if all the pestles and mortars and mills of the world were grinding and wearing away the rocks."

The amount of mineral matter transported by rivers can be estimated by examining their waters at different periods and places, and determining their solid contents. A complete analysis should take into account what is chemically dissolved, what is mechanically suspended, and what is driven or pushed along the bottom. We have already dealt with the chemically dissolved ingredients. In determinations of the mechanically mixed constituents of river water, it is most advantageous to obtain the proportion first by weight, and then from its average specific gravity to estimate its bulk as an ingredient in the water. The Ganges, according to Everest, contains during the four months of flood earthy matter in the proportion of $\frac{1}{125}$ by weight or $\frac{1}{250}$ by volume,—the mean average for the year being $\frac{1}{120}$ by weight or $\frac{1}{240}$ by volume. According to Mr Login, the waters of the Irrawaddy contain $\frac{1}{1700}$ by weight of sediment during floods, and $\frac{1}{1725}$ during a low state of the river. The most elaborate measurements and calculations yet made regarding this aspect of the operations of a river are those by Messrs Humphreys and Abbot on the Mississippi, who found, as the mean of many observations carried on continuously at different parts of the river for months together, that the average

proportion of sediment contained in the water of the Mississippi is $\frac{1}{1800}$ by weight, or $\frac{1}{3600}$ by volume. But besides the matter held in suspension, they observed that a large amount of coarse detritus is constantly being pushed along the bottom of the river. They estimated that this moving stratum carries every year into the Gulf of Mexico about 750 million cubic feet of sand, earth, and gravel. Their observations led them to conclude that the annual discharge of water by the Mississippi is 19,500,000 million cubic feet, and consequently that the weight of mud annually carried into the sea by this river must reach the sum of 813,500 million lb. Taking the total annual contributions of earthy matter, whether in suspension or moving along the bottom, they found them to equal a prism 268 feet in height, with a base of one square mile.

2. Excavating Power.—In transporting its freight of sediment a river performs a vast amount of abrasion. In the first place it rubs the loose stones against each other, breaks them into smaller pieces, rounds off their edges, reduces them to rounded pebbles and finally to sand or mud. In the next place by driving these loose materials over the rocks it wears down the sides and bottom of its channel which is thereby widened and deepened.

The familiar effect of running water upon fragments of rock, in reducing them to smoothed rounded pebbles, is expressed by the common phrase "water-worn." Every stream which descends from high rocky ground may be compared to a grinding mill; large boulders and angular blocks of rocks, disengaged by frosts, springs, and general atmospheric waste, fall into the upper end, and only fine sand and silt are discharged into the sea. M. Daubrée has instituted some ingenious experiments for ascertaining the circumstances under which angular fragments are converted into rounded pebbles with the production of sand and mud. Using fragments of granite and quartz, he caused them to slide over each other in a hollow cylinder partially filled with water, and rotating on its axis with a mean velocity of 0.80 to 1 metre in a second. He found that after the first 25 kilometres (about 15½ English miles) the angular fragments of granite had lost $\frac{1}{10}$ of their weight, while in the same distance fragments already well-rounded had not lost more than $\frac{1}{100}$ to $\frac{1}{200}$. The fragments rounded by this journey of 25 kilometres in a cylinder could not be distinguished either in form or in general aspect from the natural detritus of a river bed. A second product of these experiments was an extremely fine impalpable mud, which remained suspended in the water several days after the cessation of the movement. During the production of this fine sediment the water acted chemically upon the granite fragments, for after a day or two it was found, even though cold, to have dissolved a very sensible proportion of silicate of potash. After a journey of 160 kilometres, 3 kilogrammes (about 6½ lb avoirdupois) had yielded 33 grammes (about 50 grains) of soluble salts consisting chiefly of silicate of potash. A third product was an extremely fine angular sand consisting almost wholly of quartz, with scarcely any feldspar, almost the whole of the latter mineral having passed into the state of clay. The sand grains, as they are continually pushed onward over each other upon the bottom of a river, become rounded as the larger pebbles do. But, as M. Daubrée points out, a limit is placed to this attrition by the size and specific gravity of the grains. So long as they are carried in suspension they will not abrade each other, but remain angular; for he found that the milky tint of the Rhine at Strasburg in the months of July and August was due not to mud but to a fine angular sand (with grains about $\frac{1}{10}$ millimetre in diameter) which constitutes $\frac{1}{100000}$ of the total weight of water. Yet this sand had travelled in a rapidly flowing tumultuous river from the Swiss mountains, and had

been tossed over waterfalls and rapids in its journey. He ascertained also that sand with a mean diameter of grain of $\frac{1}{16}$ mm. will float in feebly agitated water; so that all sand of finer grain must remain angular. The same observer has noticed that sand composed of grains with a mean diameter of $\frac{1}{8}$ mm., and carried along by water moving at a rate of 1 metre per second, gets rounded, and loses about $\frac{1}{1000}$ of its weight in every kilometre travelled.

The effects of abrasion upon the loose materials on a river bed are only a portion of the erosive work performed by the stream. Where the bottom is covered with a layer of debris only the upper portion of which is pushed onward by the current, the solid rock of the river channel is there protected from waste. But this protection is only local, and is apt to be swept away from time to time by violent floods. In those parts of a river channel where the current is strong enough to keep gravel and boulders moving along, these loose materials rub down the rocky bottom over which they are driven. As the shape and declivity of the channel vary constantly from point to point, with at the same time frequent changes in the nature of its rocks, this erosive action is liable to continual modifications. While there is a general abrasion of the whole bottom over which loose debris is rolled, the erosion goes on most briskly in the numerous hollows and grooves along which chiefly these loose materials travel. Wherever an eddy occurs in which gravel is kept in gyration, erosion is much increased. The stones in their movement excavate a hole in the channel, while, as they themselves are reduced to sand and mud, or are swept out by the force of the current, their places are taken by fresh stones brought down by the stream. Such *pot-holes*, as they are termed, vary in size from mere cup-like depressions to huge cauldrons or pools. As they often coalesce by the giving way of the intervening walls between two or more of them they materially increase the deepening of the river bed.

The shape of a river channel at any given point in its course depends mainly upon the nature and structure of the material out of which it has been eroded. One of the most characteristic features of streams, whether large or small, is the tendency to wind in serpentine curves when the angle of declivity is low and the general surface of the country tolerably level. This peculiarity may be observed in every stream which traverses a flat alluvial plain. Some slight weakness in one of its banks enables the current to cut away a portion of the bank at that point. By degrees a concavity is formed, whence the water is deflected to the opposite side, there to break with increased force against the bank. Gradually a similar concavity is cut out on that side, and so, bending alternately from one side to the other, the stream is led to describe a most sinuous course across the plain. By this process, however, while the course is greatly lengthened, the velocity of the current proportionately diminishes, until it may, before quitting the plain, become a lazy, creeping stream, which in England is bordered perhaps with sedges and willows. Such meandering courses are most frequent in soft alluvial plains, but they may also be found in solid rock if the original form of the surface was tolerably flat. The windings of the gorges of the Moselle and Rhine through the table-land between Treves, Mainz, and the Siebengebirge form a notable illustration.

Abrupt changes in the geological structure or lithological character of the rocks of a river-channel may give rise to waterfalls. In many cases waterfalls have originated in lines of escarpment over which the water at first found its way, or in the same geological arrangement of hard and soft rocks by which the escarpments themselves have been produced. In the case of the falls of Niagara, for example, the stream may have fallen over the Queenstown cliff when the river first sought its way to the sea. But

much more probably the escarpment and waterfall began to arise simultaneously and from the same geological structure. As the escarpment grew in height, it receded from its starting point. The river-ravine likewise crept backward, but at a more rapid rate, and the result has been that at present the cliff worn down by atmospheric causes stands at Queenstown, while the ravine extends 7 miles further inland, with a width of from 200 to 400 yards, and a depth of from 200 to 300 feet. In this as in other cases the waterfall has cut its way backward up the course of its stream, and will continue to do so as long as the structure of the gorge continues as it is now—a thick bed or beds of limestone resting horizontally upon soft shales. The softer strata at the base are undermined, and slice after slice is cut off from the cliff over which the cataract pours. It has been estimated that at their present rate of recession the Niagara Falls must have taken about 35,000 years to cut their way backward and excavate the gorge between their present position and Queenstown. In other cases waterfalls have been produced by the existence of a harder and more resisting band or barrier of rock crossing the course of the stream, as, for instance, where the rocks have been cut by an intrusive dyke or mass of basalt. In these and all other cases the removal of the harder mass destroys the waterfall, which, after passing into a series of rapids, is finally lost in the general abrasion of the river-channel. The most marvellous river gorges in the world are those of the Colorado region in North America. The rivers there flow in ravines thousands of feet deep and hundreds of miles long, through vast tablelands of nearly horizontal strata. The Grand Cañon (ravine) of the Colorado river is 300 miles long, and in some places more than 6000 feet in perpendicular depth. The country is hardly to be crossed except by birds, so profoundly has it been tenanted by these numerous gorges. Yet the whole of this excavation has been effected by the erosive action of the streams themselves.

In the excavation of a ravine, whether by the recession of a waterfall or of a series of rapids, the action of the river is more rapid than that of the atmospheric agents. The sides of the ravine consequently retain their vertical character. But where, from the nature of the ground, the denuding action of rain, frost, and general weathering is more rapid than that of the river, a wider and open valley is hollowed out, through which the river flows, and from which it carries away the materials discharged into it from the surrounding slopes by the rain and brooks.

3. Reproductive Power.—Every body of water which when in motion carries along sediment drops it when at rest. The moment a current has its rapidity checked it is deprived of some of its carrying power, and begins to lose hold upon its sediment, which tends more and more to sink and halt on the bottom the slower the motion of the water. In the course of every brook and river there are frequent checks to the current. If these are examined, they will usually be found to be each marked by a more or less conspicuous deposit of sediment. We may notice seven different situations in which stream deposits or *alluvium* may be accumulated.

(a.) *At the foot of Mountain Slopes.*—When a rannel or torrent descends a steep declivity it tears down the soil and rocks, cutting a deep gash out of the side of the mountain. On reaching the level ground at the base of the slope the water, abruptly checked in its velocity, at once drops its coarser sediment, which gathers in a fan-shaped pile or cone, with the apex pointing up the water course. Huge accumulations of boulders and shingle may thus be seen at the foot of such torrents,—the water flowing through them often in several channels which re-unite in the plain beyond.

(b.) *In River-beds.*—This is characteristically shown in many of the rivers of Britain, by the accumulation of a bed

of sand or shingle at the concave side of each sharp bend of the river course. While the main current is making a great sweep round the opposite bank, the water lingers along the inner side of the curve and drops there its freight of loose detritus, which, when laid bare in dry weather, forms the familiar sand-bank or shingle beach. Again, when a river, well supplied with sediment, leaves rough ground where its course has been rapid, and enters a region of level plain, it begins to drop its burden on its bed, which is thereby heightened, till sometimes, as in parts of the courses of the Po, Adige, and Brenta across the plains of Lombardy, it is higher than the surrounding level region. This could not happen were it not that in floods a river deposits sediment along its banks, which are thus also heightened so as to retain the river in its ordinary state. But in such cases, if man lives in the margin of the river, he needs all his skill and labour to keep the banks secure. And even with his utmost efforts the river will now and then break through, sweeping down the barrier which it has itself made, as well as any additional embankments constructed by him, and carrying its flood far and wide over the plain. Left to itself, the river would incessantly shift its course, until in turn every part of the plain had been again and again traversed. It is indeed in this way that a great alluvial plain is gradually levelled and heightened.¹

(c.) *On River-banks and Flood-plains*.—This deposit is partly implied in the action described in the foregoing paragraph. It is laid down on the level tracts or flood-plain over which a river spreads in flood, and consists usually of fine silt, mud, earth, or sand, though close to the river it may be partly made up of much coarser materials. When a flooded river overflows, the portions of water which spread out on the plains, by losing velocity and consequently power of transport, are compelled to let fall some or all of their mud and sand. If the plains happen to be covered with woods, bushes, scrub, or even tall grass, the vegetation acts the part of a sieve, and filters the muddy water, which may rejoin the main stream comparatively clear. Every flood increases the height of the plain, until, partly from this cause and partly, in the case of a rapid stream, from the erosion of its bed, the river can no longer overspread it. As the channel is more and more deepened, the river continues, as before, to be liable from inequalities in the material of its banks, sometimes of the most trifling kind, to be turned from side to side in wide curves and loops, and cuts into its old alluvium, making eventually a newer plain at a lower level. Continued erosion carries the channel to a still lower level, where the stream can attack the later alluvial deposit, and form a still lower and newer one. The river comes by this means to be fringed with a series of terraces, each of which represents a former flood-level of the stream. In Britain it is common to find three such terraces, but sometimes as many as six or seven or even more may occur. In North America the river terraces exist on so grand a scale that the geologists of that country have named one of the later periods of geological history, during which those deposits were formed, the Terrace Epoch. In the attempt to reconstruct the history of the old river-terraces of a country, we have to consider whether they have been entirely cut out of older alluvium (in which case, of course, the valleys must have been as deep as now before the formation of the terraces), whether they afford any indications of having been formed during a period of greater rainfall, when the rivers were larger than at present, whether they point to any upheaval of the interior of the country which would accelerate the erosive action of the streams, or to any depression of the

interior or rise of the seaward tracts, which would diminish that action and increase the deposition of alluvium. Professor Dana has connected those of America with the elevation of the axis of that continent.

(d.) *In Lakes*.—When a river enters a lake its current is at once checked, and its sediment begins to gather over the lake bottom. If the lake be long enough in proportion to the volume of the river, the whole of the detritus may be deposited, so that, at its outflow, the river becomes as clear as when its infant waters began their course from the springs, snows, and mists of the far mountains. Thus the Rhone enters the Lake of Geneva turbid and impetuous, but it escapes at Geneva as blue translucent water. Its sediment is laid down on the floor of the lake, and chiefly at the upper end. Hence, lakes act as filters or sieves to intercept the sediment which is travelling in the rivers from the high grounds to the sea. If we look down from a height even upon a small lake among mountains, we observe that at the mouth of each torrent or brook which enters it there lies a little tongue of flat land (a true *delta*), through which the streamlet winds in one or more branches before mingling its waters with those of the lake. Each of these tongues consists of alluvium, laid down in obedience to the same law which governs the formation of river alluvium elsewhere, and continually creeping further out from the land as the deposit of sediment advances. Two streams entering a lake from opposite sides may join their alluvia so as to divide the lake into two, like the once united lakes of Thun and Brienz at Interlaken. Or the lake may be finally filled up altogether, as has happened in innumerable cases in all mountainous countries; the hilly tracts of Britain, for example, furnish abundant illustrations of every stage in this process. Where a large river with abundant sediment enters an important lake (as the Rhone at the head of the Lake of Geneva), the accumulation of its alluvium or delta may quite rival that of a great river in the sea, as described in paragraph (f.) below.

(e.) *Bars and Lagoon-Barriers*.—If we take a broad view of the degradation of the land, we must admit that the deposit of any sediment on the land is only temporary; the inevitable destination of all this material is the ocean. Most rivers which enter the sea have their mouths crossed by a bar of gravel, sand, or mud. The formation of this barrier results from the conflict between the river and the ocean. Although the muddy fresh water floats on the heavier salt water, its current is lessened, and it can no longer push along the mass of detritus on its bed. It has been ascertained, moreover, that, though fresh water can retain for a long while fine mud in suspension, this sediment is rapidly thrown down when the fresh is mixed with saline water. Hence, apart from the necessary loss of transporting power by the checking of the river current at the mouth, the mere mingling of a river with the sea must of itself be a cause of the deposit of sediment. But a large body of fresh water may float for a long distance before it is thoroughly mingled with the heavier water of the ocean. Ultimately, however, the fine detritus dropped by a river, together with the coarser materials on the bottom, are arrested by the sea. Moreover, in many cases the sea itself piles up great part of the sand and gravel of the bar. Heavy river-floods push the bar farther to sea, or even temporarily destroy it; storms from the sea, on the other hand, drive the bar farther up the stream. Another remarkable illustration of the contest between the alluvium-carrying streams and the land-eroding ocean is shown by the vast lines of bar or bank which, both in the Old World and the New, stretch along the coast. The streams do not flow straight into the sea, but run sometimes for many miles parallel to the coast, accumulating behind the barriers into broad

¹ It is in the north of Italy that the struggle between man and nature in this department has been most persistently waged. See on this subject Lombardini in *Ann. des Ponts et Chaussées*, 1847.

and long lagoons, but eventually breaking through the barriers of alluvium and entering the sea. The lagoons of the Italian coast and of the Baltic near Dantzic are familiar examples. A conspicuous series of these alluvial bars fronts the American mainland for many hundred miles round the Gulf of Mexico and the shores of Florida, Georgia, and North Carolina. A space of several hundred miles on the east coast of India is similarly bordered. M. E. de Beaumont, indeed, has estimated that about a third of the whole of the coast-lines of the continents is fringed with such alluvial bars.

(*r*.) *Deltas in the Sea*.—The tendency of sediment to accumulate in a tongue of flat land when a river loses itself in a lake is exhibited on a far vaster scale where the great rivers of the continents enter the sea. It was to one of these maritime accumulations, that of the Nile, that the Greeks gave the name Delta, from its resemblance to their letter Δ , with the apex pointing up the river, and the base floating the sea. This shape being the common one in all such alluvial deposits at river mouths, the term delta has come to be always applied to them. A delta therefore consists of successive layers of detritus, brought down from the land and spread out in the sea at the mouth of a river until they reach the surface, and then, partly by growth of vegetation and partly by flooding of the river, form a plain, of which the inner and higher portion comes eventually to be above the reach of the floods. Large quantities of drift-wood are often carried down, and bodies of animals are swept off to be buried in the delta, or even to be floated out to sea. Hence, in deposits formed at the mouths of rivers, we may always expect to find terrestrial organic remains.

When a river enters upon the delta-portion of its course it assumes a new character. In the previous parts of its journey it is always being augmented by tributaries; but now it begins to split up into branches, which wind to and fro through the flat alluvial land, often coalescing and thus enclosing insular spaces of all dimensions. The feeble current, no longer able to bear along all its weight of sediment, allows much of it to sink to the bottom and to gather over the tracts which are from time to time submerged. Hence many of the channels get choked up, while others are opened out in the plain, to be in turn abandoned, and thus the river restlessly shifts its channels. The seaward ends of at least the main channels grow outwards by the constant accumulation of detritus pushed into the sea, unless this growth chances to be checked by any marine current sweeping past the delta.

The European rivers furnish many excellent illustrations of delta-growth. Thus the Rhine, Meuse, Sambre, Scheldt, and other rivers have formed the wide maritime plain of Holland and the Netherlands. The Rhone has deposited an important delta in the Mediterranean Sea. The upper reaches of the Adriatic Sea are being rapidly shallowed and filled up by the Po, Adige, and other streams. Thus Ravenna, originally built in aagoon like Venice, is now 4 miles from the sea. The port of Adria, so well known in ancient times as to have given its name to the Adriatic, is now 14 miles inland, while in other parts of that coast-line the breadth of and gained within the last 1800 years has been as much as 20 miles. On the opposite side, also, of the Italian peninsula, great additions have been made to the coast-line within the historical period. It is computed that the Tuscan rivers lay down as much as 12 million cubic ards of sediment every year within the marshes of the faenoma. The "yellow" Tiber, as it was aptly termed by the Romans, owes its colour to the abundance of the diment which it carries to sea. It has long been adding the coast-line at its mouth at the rate of from 12 to 13

feet per annum. Hence the ancient harbour of Ostia is now more than 3 miles inland. Its runs are at present (1879) being excavated, but every flood of the river leaves a thick deposit of mud on the streets and on the floors of the uncovered houses. Whence it would seem that the Tiber has not only advanced its coast-line, but has raised its bed on the plains by the deposit of alluvium, so that it now overflows places which, 2000 years ago, could not have been so frequently under water.¹ In the Black Sea a great delta is rapidly growing at the mouths of the Danube. At the Kiha outlets the water is shallowing so fast that the lines of soundings of 6 feet and 30 feet are advancing into the sea at the rate of between 300 and 400 feet per annum.²

The typical delta of the Nile has a seaward border 180 miles in length, the distance from which to the apex of the plain where the river bifurcates is 90 miles. That of the Mississippi contains an area of 40,000 square miles. The untied delta of the Ganges and Brahmaputra covers a space of between 50,000 and 60,000 square miles, and has been bored through to a depth of 481 feet.

(*g*.) *Sea-borne Sediment*.—Although more properly to be noticed under the section on the sea, the final course of the materials worn by rains and rivers from the surface of the land may be referred to here. By far the larger part of these materials sinks to the bottom close to the land. It is only the fine mud carried in suspension in the water which is carried out to sea, the distance depending on the velocity of the stream, the specific gravity and shape of the particles of the mud, and the help or hindrance given by marine currents. The sea fronting the Amazon is discoloured for 300 miles by the mud of that river. The soundings taken by the "Challenger" brought up land-derived detritus from depths of 1500 fathoms,—several hundreds of miles distant from the nearest shores.

The amount of material carried by a river into the sea may be taken as the measure or gauge of the general lowering of the surface of the basin drained by the river. If we ascertain the annual quantity of mineral matter thus delivered into the sea, and know the superficial extent of ground from which it has been derived, the one sum divided by the other gives the extent by which the mean level of the country is reduced in one year. Both the fine mud mechanically suspended in the water and the salts dissolved in it should be taken into account, as well as the coarser detritus pushed along the bottom. It is the mechanically suspended mud which has generally been measured. According to the data of Messrs Humphreys and Abbot, already cited, the proportion of sediment in the Mississippi is $\frac{1}{1000}$ by weight, or $\frac{1}{10000}$ by volume. The annual discharge of sediment is 7,459,267,200 cubic feet, and the drainage basin 1,147,000 square miles. This is equal to a loss of $\frac{1}{10000}$ of a foot of rock from the general surface of the drainage basin in 1 year, or 1 foot in 6000 years. Other rivers work faster than this rate. The Ganges has been estimated to remove 1 foot of rock from its drainage area in 2358 years, and the Po 1 foot in 729 years. Such computations are at the best only approximations to the truth, but they are useful in showing how great an amount of change must be effected even within comparatively short geological periods by the various agents which are disintegrating the surface of the land.

¹ See an interesting article by Professor Charles Martins on the Agnes-Motes, in *Revue des Deux Mondes*, 1874, p. 780. The present writer accompanied the distinguished French geologist on the occasion of his visit to Ostia in the spring of 1873, and was much struck with the proof of the rapidity of deposit in favourable situations. In the article just cited some valuable information is given regarding the progress of the delta of the Rhone in the Mediterranean.

² Hartley, *Min. of Proc. Inst. Civ. Engin.*, xxvii, 216.

§ 4. *Lakes.*

Depressions filled with water on the surface of the land, and known as lakes, occur abundantly in the northern parts of both hemispheres, and more sparingly, but often of large size, in warmer latitudes. They do not belong to the normal system of erosion in which running water is the prime agent, and to which the excavation of valleys and ravines must be attributed. On the contrary, they are exceptional to that system, and the constant tendency of running water is to fill them up. Their origin, therefore, must be sought among some of the other geological processes. See part vii.

Lakes are conveniently classed as fresh or salt. Those which possess an outlet contain in almost all cases fresh water, those which have none are usually salt.

1 *Fresh-water Lakes*—These, in a vast number of cases, are simply depressions or expansions of the valleys in which they lie. They receive a river at the upper end, together probably with many minor tributaries from the sides, and let the accumulated waters overflow at the lower end. In all these cases, they act as filters for the river water, allowing its sediment to settle, and discharging it purified at the outflow, to continue its course of erosion and mud-making down the valley. A river which flows through a succession of lakes cannot carry much sediment to the sea, unless it has a long course to run after it has passed the lowest lake, and receives one or more muddy tributaries. But the sediment which would have reached the sea and gone to form a delta or deposit on the sea-bed serves its purpose in contributing to fill up the lakes. Hence it is rare to find any lake with an inflowing and outflowing river, where proofs of the gradual encroachment of the land upon the water may not be gathered.

In other cases lakes do not lie in the natural drainage lines of a country, but are scattered apparently at random over the surface, fed by springs, rains, and streamlets from the slopes, or, if of large size, lying as great basins, receiving the collected waters of a wide region, and forming in this way the source out of which full-formed rivers emerge. From the little tarns of Wales and the lochans of Scotland a series may be traced, through innumerable grades of size and form, in Scandinavia, Finland, and Canada, till we reach such vast sheets of inland water as Lakes Huron, Erie, and Superior, and the great equatorial lakes of Africa. In lakes of this kind also the process of filling up may often be traced. Each tributary stream pushes its delta into the water. Where the lakes are shallow, and lie in temperate countries, vegetation comes in to aid in the conversion of the water, first into marsh, then into peat-bog, and finally into dry ground. In Scotland during the last few centuries great changes of this kind have been going on.

On large lakes the wind throws the water into waves which almost rival those of the ocean in size and destructive power. Beaches, sand-dunes, shore-cliffs, and the other familiar features of the meeting line between land and sea reappear along the margins of such great fresh-water seas as Lake Superior.

Three geological functions of lakes are (1) to arrest and equalize the drainage by regulating the outflow and preventing or lessening the destructive effects of floods¹; (2) to filter river water and permit of the undisturbed accumulation of new deposits, which in some modern cases may cover thousands of square miles of surface, and might attain

a thickness of nearly 3000 feet (Lake Superior has an area of 32,000 square miles, Lago Maggiore is 2800 feet deep); (3) to furnish an abode for a lacustrine fauna and flora, to receive the remains of the plants and animals washed down from the surrounding country, and to entomb all these organisms in the growing deposits, so as to preserve a record of the terrestrial life of the period. The deposits in lakes consist of alternations of sand, silt, mud, and gravel, with occasional irregular seams of vegetable matter, and layers of calcareous marl formed from the accumulation of lacustrine shells, *Entomostraca*, &c. In a lake receiving much sediment there will be little or no marl formed, at least not during the time when the sediment is being deposited. In clear lakes, on the other hand, where there is very little sediment or where it only comes occasionally at wide intervals of flood, beds of white marl, formed entirely of organic remains, may gather on the bottom to a depth of many yards.

2. *Salt Lakes* may be divided into two classes—(a) those which owe their saltiness to the evaporation and concentration of the fresh water poured into them by their feeders; and (b) those which were originally parts of the ocean. Salt lakes of the first kind are abundantly scattered over the inland areas of drainage in the heat of continents, as in the great Lake of Utah, and numerous other minor lakes in North America, and the abundant salt lakes of the great plateau of Central Asia. These sheets of water were doubtless fresh at first, but they have progressively increased in salinity, because though the water is evaporated as fast as it is received, there is no escape for the dissolved salts, which consequently remain in the increasingly concentrated liquid. Salt lakes of the second class are comparatively few in number. In their case portions of the sea have been isolated by movements of the earth's crust, and these detached areas, exposed to evaporation, which is only partially compensated by inflowing rivers, have shrunk in level, and at the same time have sometimes grown much saltier than the parent ocean. The Caspian Sea, 180,000 square miles in extent, and with a maximum depth of from 2000 to 3000 feet, is a magnificent example. The shells are chiefly the same as those still living in the Black Sea. Banks of them may be traced between the two seas, with salt lakes and marshes and other evidence to prove, not only that the Caspian was once joined to the main ocean, but that a great firth ran up between Europe and Asia, and possibly stretched completely across what are now the steppes and plains of the Tundras till it merged into the Arctic Sea. Even at present, by means of canals connecting the rivers Volga and Dwina, vessels can pass from the Caspian into the White Sea. But the surface of the Caspian is now more than 80 feet below that of the Black Sea. At present the amount of water supplied by rivers to the Caspian just balances that removed by evaporation, so that the level appears to be no longer sinking. But though, owing to the enormous volume of fresh water poured into it by these rivers, the Caspian is not as a whole so salt as the main ocean, and still less so than the Mediterranean, nevertheless the inevitable result of evaporation is there manifested. Along the shallow pools which border this sea a constant deposition of salt is taking place, forming sometimes a pan or layer of rose-coloured crystals on the bottom, or gradually getting dry, and covered with drift sand. This concentration of the water is still more marked in the great offshoot called the Karaboghaz, which is connected with the middle basin of the Caspian by a channel 150 yards wide and 5 feet deep. Through this narrow mouth there flows from the main sea a constant current, which Von Baer estimated to carry daily into the Karaboghaz 350,000 tons of salt. An appreciable increase of the saltiness of that gulf has been noticed; seals, which once frequented it, have forsaken its barren shores. Layers of salt are gathering on the mud at

¹ Winds, by blowing strongly down the length of a lake, sometimes considerably increase for the time being the volume of the outflow. If this takes place coincidentally with a heavy rainfall, the flood of the river is greatly augmented. These features are noticed in Loch Tay (D. Stevenson, *Reclamation of Land*, p. 14). Hence, though, on the whole, lakes tend to moderate floods in the outflowing rivers, they may by a combination of circumstances sometimes increase them.

the bottom, and the sounding-line, when scarcely out of the water, is covered with saline crystals¹. These facts furnish an illustration of the circumstances under which the rock-salt deposits in the New Red Sandstone and other geological formations were probably accumulated.

The following table shows the proportion of the saline materials in the waters of some salt lakes.—

	Elton Lake, Kazian Steppes, (Russia)	Interich Lake (Siberia)	Dead Sea (G. G. fathoms)	Caspian Sea (Fathoms)
Chloride of Sodium	74	219	71	0.5673
" Magnesium	10.5	17	11.8	0.0632

II. FRESH WATER IN THE SOLID STATE.—ICE

Fresh water under ordinary circumstances, when it reaches a temperature of 32° Fahr., passes into the solid state by crystallizing into ice. In this condition it performs a series of important geological operations before being again melted and relegated to the general mass of liquid terrestrial waters. Five conditions under which ice occurs on the land deserve notice, viz, frost, frozen rivers and lakes, hail, snow, and glaciers.

1. *Frost*.—Water in freezing expands. If it be confined in such a way that expansion is impossible, it remains liquid even at temperatures far below the freezing point, but the instant that the pressure is removed this chilled water becomes solid ice. There is a constant effort on the part of the water to become solid, and very considerable pressure is needed to counterbalance its expansive power. The lower the temperature the greater this exerted pressure becomes. At a temperature of 30° Fahr. the pressure must amount to 146 atmospheres, or the weight of a column of ice a mile high, or 138 tons on the square foot. Consequently when the water freezes at a lower temperature its pressure on the walls of its enclosing cavity must exceed 138 tons on the square foot. Bomb-shells and cannon filled with water and hermetically sealed have been burst in strong frosts by the expansion of the freezing water within them. It is easy to see, therefore, that we have here a geological agent of great potency. It is true that in nature the enormous pressures which can be obtained artificially occur rarely or not at all, because the spaces into which water penetrates can hardly ever be so securely closed as to permit the water to be cooled down very considerably below 32° Fahr. before freezing. Still ice forming at even two or three degrees below the freezing point exerts an enormous disruptive force.

Soils and rocks are all porous, and usually contain a good deal of moisture. When frost congeals this interstitial water, the particles of the soil or rock are pushed asunder by the expanding ice; their cohesion is loosened or destroyed, so that when a thaw comes, they seem as if they have been ground down in a mortar. Water lodges also in the numerous joints and crevices of rocks. Freezing there, it exerts great pressure upon the walls between which it lies, pushing them asunder as if a wedge were driven between them.

When this ice melts, the separated masses do not return to their original position. Their centre of gravity in successive winters becomes more and more displaced, until the sundered masses fall apart. In mountainous districts, where the winters are severe, and in high latitudes, a great deal of waste is thus produced on exposed cliffs and loose blocks of rock. Some measure of its magnitude may be seen in the heaps of angular rubbish which in these regions are so frequently to be met with at the foot of crags and steep slopes. At Spitzbergen and on the coast of Greenland the amount of destruction caused by frost is enormous. The short and warm summer, melting the snow, fills the pores and joints of the rocks with water, which when it freezes splits off large blocks of rock from the hills, and sends them to the base of the declivities, where they are further broken up by the same cause.

2. *Frozen Rivers and Lakes*.—In countries where the winter temperature falls considerably below 32° Fahr., the lakes and rivers become solidly frozen over. The amount of geological change effected during the process is probably hardly appreciable. But when the ice breaks up in spring its power as a geological agent becomes apparent. In lakes, such as Lake Superior, the ice in forming encloses beach-pebbles and boulders, and when thaw sets in, floats these off, so as either to drop them in deeper water or to strand them on some other part of the coast. Should a gale arise during the breaking up of the ice, vast piles of the latter, with mangled gravel and boulders, may be driven ashore and pushed up the beach. By this means blocks of stone, even of considerable size, are sometimes forced to a great height inland on some of the Canadian lakes, tearing up the soil on their way, and helping to form a bank above the water level. It has been observed that during a severe frost ice occasionally forms on the bottoms of rivers where it encloses stones and large boulders. These are borne up to the surface in cakes of ground-ice to join the rest of the superficial ice-borne detritus. Great damage is frequently done to quays and bridges in Canada by masses of river-ice driven against them on the arrival of spring. Reference has already been made to the increased power of transport and erosion acquired by rivers liable to be frozen over, and especially when their ice is broken up in the higher parts of their courses, before it gives way in the lower.

3. *Hail*.—When rain or aqueous vapour is cooled down in the atmosphere to the freezing point of water, it is frozen, and falls to the earth as hail or snow. The formation of hail is not yet well understood. It is chiefly in summer and during thunderstorms that hail falls. When the pellets of ice are frozen together so as to reach the ground in lumps as large as a pigeon's egg, or larger, great damage is often done to cattle, flying birds, and vegetation. Trees have their leaves and fruit torn off, and farm crops are beaten down.

4. *Snow*.—In those parts of the earth's surface where, either from geographical position or from elevation into the upper cold regions of the atmosphere, the mean annual temperature is below the freezing point, the condensed moisture falls chiefly as snow, and remains in great measure unmelted throughout the year. A line can be traced below which the summer heat suffices to cause the disappearance of the snow, but above which the snow continues to cover the whole or great part of the surface. This line has received the name of the snow-line, or line of perpetual snow. It comes down to the sea within the polar circles. Between these limits it rises gradually in level till it reaches its highest elevation in tropical latitudes. In northern Scandinavia it is less than 3000 feet above the sea. None of the British mountains quite reach it. In the Alps it stands at 8500 feet, on the Andes at 18,000 feet, and on the northern slopes of the Himalayas at 19,000 feet.

¹ Carpenter, *Journ. Geog. Soc.*, vol. xviii., No. 4, quoting from Von Baer's "Kaspische Studien," in *Bull. Acad. Sci. St. Petersburg*, 1855-6.

Snow exhibits two different kinds of geological behaviour, one conservative, the other destructive. Lying stationary and unmelted it exercises a protective influence on the face of the land, shielding rocks, soils, and vegetation from the effects of frost. On low grounds this is doubtless its chief function. When snow falls in a partially melted state it is apt to accumulate on branches and leaves, until by its weight it breaks them off, or even bears down entire trees. Snow which falls thickly on steep mountain slopes is frequently during spring and summer detached in large sheets. These rush down the declivities as *avalanches*, and often create much destruction of trees, soil, crops, and houses in their course. Another indirect effect of snow is seen in the sudden rise of the rivers when warm weather rapidly melts the mountain snows. Many summer floods are caused in this way in Switzerland.

5. *Glaciers*.—(1.) Nature and Origin.—A glacier is a river of ice formed by the slow movement and compression of the snow which by gravitation creeps downward into a valley descending from a snow-field. The structure and physics of glaciers are described elsewhere (see *GLACIERS*). From a geological point of view these ice-rivers may be regarded as the drainage of the snow-fall above the snow-line, as rivers are the drainage of the rainfall. In a mountainous region, such as the Alps, or a table-land like Scandinavia, where a considerable mass of ground lies above the snow-line, three varieties of glaciers have been observed. (a.) Glaciers of the first order, where the ice-river comes down well below the snow and extends into the valley, even it may be far below the upper limits of cultivation, or in northern regions approaches or even reaches the sea. In the Alps such glaciers may be 20 or 30 miles long, by a mile or more wide, and 600 feet or more deep. (b.) Glaciers of the second order, which hardly creep beyond the high recesses wherein they are formed, and do not therefore reach as far as the nearest valley. Many beautiful examples of this type may be seen along the steep declivities which intervene between the snow-covered plateau of Arctic Norway and the sea. (c.) Re-cemented glaciers, consisting of fragments which fall from an ice-cliff crowning precipices of rock, and are re-frozen at the bottom into a solid mass, creeping downward as a glacier usually of the second order. Probably the best illustrations in Europe are furnished by the Nus Fjord, and other parts of the north of Norway. In some cases a cliff of blue ice appears at the top of the precipice,—the edge of the great “*snee-fond*,” or snow-field,—while several hundred feet below, in the corrie or cwm at the bottom, lies the re-cemented glacier (*glacier remanié* of the Swiss), white at its upper edge, but acquiring somewhat of the characteristic blue gleam of compact ice as it moves towards its lower margin.

But it is in high Arctic, and still more in Antarctic, latitudes that land-ice, formed from the drainage of a great snow-field, attains its greatest dimensions. The land in these regions is completely buried under an ice-cap, which ranges in thickness up to a depth (in the South Polar circle) of 10,000 feet (2 miles) or even more. Greenland lies under such a pall of snow that all its inequalities, save the mere steep mountain peaks, are concealed. The snow creeping down the slopes, and mounting over the minor hills, passes beneath by pressure into compact ice. From the main valleys great glaciers like vast tongues of ice, 2000 or 3000 feet thick, and sometimes 50 miles or more in breadth, push out to sea, where they break off in huge fragments, which float away as icebergs.

A glacier, like a river, is always in motion, though so slowly that it seems to be solid and stationary. The motion also, like that of a river, and for the same reason, is unequal in the different parts, the centre moving faster than the sides and bottom. This important fact was first ascertained

through accurate measurement by J. D. Forbes, who found that in the Mer de Glace of Chamouni, the mean daily rate of motion in the summer and autumn was from 20 to 27 inches in the centre, and from 13 to 19½ near the side. The consequence of this differential motion is seen in the arrangement of the lines of rubbish thrown down at the end of a glacier, which often present a horse-shoe shape, corresponding to that of the end of the ice by which they were discharged.

There are some features of geological importance also in the behaviour of the ice as it descends its valley. When it has to travel over a very uneven floor, some portions may get embayed, while overlying parts slide over them. A massive ice-sheet may thus have many local eddies in its lower portions, the ice there even travelling for various distances, according to the nature of the ground, obliquely to the general flow of the main mass. In descending by a steep slope from an upper to a lower and more level part of its course, a glacier becomes a mass of fissured ice in great confusion. It descends by a slowly creeping ice-fall, where a river would shoot over in a rushing waterfall. A little below the fall the fractured ice is pressed together again into a solid mass as before. The body of the glacier throughout its length is traversed by a set of fissures called *crevasses*, which, though at first as close-fitting as cracks in a sheet of glass, widen by degrees as the glacier moves on, till they form wide yawning chasms, reaching, it may be, to the bottom of the ice, and travelling down with the glacier, but apt to be effaced by the pressing of their walls together again as the glacier winds down its valley. The glacier continues to descend until it reaches that point where the supply of ice is just equalled by the liquefaction. There it ends, and its place down the rest of the valley is taken by the tumultuous river of muddy water which escapes from under the melting extremity of the ice. A prolonged augmentation of the snow-fall will send the foot of the glacier further down the valley, a diminution of the snowfall with a general rise of temperature will cause it to retreat farther up.

(2.) Work done by Glaciers.—Glaciers have two important geological tasks to perform,—(1) to carry the debris of the mountains down to lower levels; and (2) to erode their beds.

a. *Transport*.—This takes place chiefly on the surface of the glacier. Descending its valley, the glacier receives and bears along on its margin the earth, stones, and rubbish which, loosened by frost, or washed down by rain and rills slip from the cliffs and slopes to the level of the ice. In this part of its work the glacier resembles a river which carries down branches and leaves from the woods on its banks. Most of the detritus rests on the surface of the ice. It includes huge masses of rock, sometimes as big as a large cottage, all which, though seemingly at rest, are slowly travelling down the valley with the ice, and liable at any moment to slip into the crevasses which may open below them. When they thus disappear they may descend to the bottom of the ice, and move with it along the rocky floor which is no doubt the fate of the smaller stones and sand. But the large stones seem sometimes at least to be cast up again by the ice to the surface of the glacier at a lower part of its course. Whether, therefore, on the ice, in the ice, or under the ice, a vast quantity of detritus is continually travelling with the glacier down towards the plains. The rubbish lying on the surface is called *moraine* stuff. Naturally it accumulates on either side of the glacier, where it forms the so-called *lateral moraine*. When two glaciers unite, their two adjacent lateral moraines are brought together, and travel thereafter down the centre of the glacier as a *medial moraine*. A glacier, formed by the union of many tributaries in its upper parts, may have

many medial lines of moraine, so many indeed as sometimes to be entirely covered with debris to the complete concealment of the ice. At such parts the glacier resembles a bare field or earthy plain rather than a solid mass of clear ice of which only the surface is dirty with rubbish. At the point where the glacier ends, the pile of loose materials is tumbled upon the valley in what is called the *terminal moraine*.

In such comparatively small and narrow ice-sheets as the present glaciers of Switzerland, the rock-bottom on which the ice moves is usually, as far as it can be examined, swept clean by the trickle or rush of water over it from the melting ice. But when the ice does not flow in a mere big drain (which, after all, the largest Alpine valley really is), but overspreads a wide area of uneven ground, there cannot fail to be a great accumulation of rubbish here and there underneath it. When the broad central plain of Switzerland between the Alps and the Jura was filled with ice, the latter certainly pushed a vast deal of mud, sand, and stones over the floor of the valley. This material is known to Swiss geologists as the *moraine profonde* or *Grundmoraine*.¹

When from any cause a glacier diminishes in size, it may drop its blocks upon the sides of its valley, and leave them there sometimes in the most threatening positions. Such stranded stones are known as *perched blocks*. They abound in the Swiss valleys, extending even across the great plain of Switzerland, and appearing in numbers high upon the flanks of the Jura. Since the latter mountains consist chiefly of limestone, and the blocks are of various crystalline rocks belonging to the higher parts of the Alps, the proof of transport is irrefragable. The agent of removal is now recognized to have been an enormous extension of the glacier system of the Alps, whereby the whole country was buried under snow and ice. Similar evidence abounds in the valleys among the mountainous parts of Britain, as well as in other parts of Europe and America, no longer the abode of glaciers.

b. Erosion—The manner in which glacier ice erodes its channel differs in many respects from that in use by any other geological agent, and forms therefore one of the distinguishing features of ice-action. This erosion is effected not by the mere contact and pressure of the ice upon the rocks, though undoubtedly fragments of rock must now and then be detached from this cause. It is by means of the fine sand, stones, and blocks of rock, which fall between the ice and the rocks on which it moves, that the grinding work of the glacier is done. These materials, held by the ice as it creeps along, are pressed against the rocky sides and bottom of the valley so firmly and persistently as to descend into each little hollow and mount over each ridge, yet all the while moving along steadily in one dominant direction with the general movement of the glaciers. As a result, the most compact resisting rocks are ground down, smoothed, polished, and striated. The striae vary from such fine lines as may be made by the smallest grains of quartz up to deep ruts and grooves. They sometimes cross each other, one set partially effacing an older one, and thus pointing to shifts in the movement of the ice. On the retirement of the glacier, hummocky bosses of rock having smooth undulating forms like dolphins' backs are conspicuous. These have received the name of *roches moutonnées*. The stones by which this scratching and polishing are effected suffer in exactly the same way. They are ground down and striated, and since they must move in the line of least resistance, or "end on," their

striae run in a general sense lengthwise. It will be seen, when we come to notice the traces of former glaciers, how important is the evidence given by these striated stones.

As rocks present great diversities of structure and hardness, and consequently vary much in the resistance they offer to denudation, they are necessarily worn down unequally. The softer, more easily eroded portions are scooped out by the grinding action of the ice, and basin-shaped or various irregular cavities are dug out below the level of the general surface. Similar effects may be produced by an augmented excavating power of a glacier, as where the ice is strangled in some narrow part of a valley, or where, from change in declivity, it is allowed to accumulate in greater mass as it moves more slowly onward. Such hollows, on the retirement of the ice, become receptacles for water, and form pools, tarns, or lakes, unless indeed they chance to have been already filled up with glacial rubbish. It is now some years since Professor A. C. Ramsay drew attention to this peculiar power of land-ice, and affirmed that the abundance of excavated rock-basins in northern Europe and America was due to the fact that these regions had been extensively eroded by sheets of land-ice. This glaciation was due not to independent glaciers but to the pressure and grinding power of vast masses of continental ice. In short the more northern parts of Europe and North America must have been in a condition like that of North Greenland at the present day. It is therefore among the ice-fields of Greenland rather than among the valley glaciers of isolated mountain-groups that we ought to look for analogies to the operations which produced the widespread general glaciation of the period of the rock-basins. A single valley-glacier retires towards its parent snow-field as the climate ameliorates, leaving its *roches moutonnées*, moraine-mounds, and rock-basins, yet at times discharging its water-drainage in such a way perhaps as to sweep down the moraine-mounds, fill up the basins, bury the ice-worn hummocks of rock, and strew the valley with gravel, earth, sand, and big blocks of rock. Hence the actual floor of the glacier is apt to be very much obscured. But in the case of a vast sheet of land-ice covering continuously a wide region, there can be but little superficial debris. When such a mass of ice retires it must leave behind it an ice-worn surface of country more or less strewn with the subsoil which accumulated under the ice and was pushed along by it. This infra-glacial detritus forms the *Grundmoraine* (*moraine profonde*) or bottom moraine. We know as yet very little regarding its formation in Greenland. Most of our knowledge regarding it is derived from a study of the till or boulder-clay of Britain, which is believed to represent the bottom moraine of an ancient ice-sheet. In countries where true boulder-clay occurs, numerous rock-basins are commonly to be met with among the uncovered portions of the rocks.

The abundant fine sediment which gives the characteristic milky turbidity to all streams that escape from the melting ends of glaciers is an index of the amount of erosion unceasingly effected by the ice. From the end of the Aar glacier, for example, though by no means one of the largest in Switzerland, it has been estimated that there escape every day in the month of August 2 million cubic metres (440 million gallons) of water, containing 284,374 kilogrammes (280 tons) of sand.

B. OCEANIC WATERS.

The area, depth, temperature, density, and composition of the sea have been already treated of in part ii. Viewed as a dynamical agent in geology, the ocean may be studied under two aspects—(1) its movements, and (2) its geological work.

¹ The present writer examined in 1869 a characteristic section of it near Solothurn, full of scratched stones, and lying on the striated pavement of rock to be immediately described as further characteristic of ice-action.

I. MOVEMENTS OF THE OCEAN.

These may be grouped as—(1) tides, (2) currents, and (3) waves.

1. *Tides*.—These are oscillations of the mass of the oceanic waters caused by the attraction of the sun and moon. We have at present to deal with them merely in so far as their geological bearings are concerned. In a wide deep ocean the tidal elevation probably produces no perceptible geological change. It passes at a great speed, in the Atlantic its rate is 500 geographical miles an hour. But as this is merely the passing of an oscillation whereby the particles of water are gently raised up and let down again, there can hardly be any appreciable effect upon the deep ocean bottom. When, however, the tidal wave enters a narrow and shallow sea, it has to accommodate itself to a smaller channel, and encounters more and more the friction of the bottom. Hence, while its rate of motion is diminished, its height and force are increased. It is in shallow water and along the shores of the land that the tides acquire their main geological importance. They there show themselves in an alternate advance upon and retreat from the coast. Their upper limit has received the name of *high-water mark*, their lower that of *low-water mark*, the space between being termed the *beach*. If the coast is precipitous, a beach can only occur in the shelving bays and creeks, since elsewhere the tides will rise and fall against a face of rock, as they do on the piers and bulwarks of a port. On such rocky coasts the line of high water is sometimes admirably defined by the grey crust of barnacles adhering to the rocks. Where the beach is flat, and the rise and fall of the tide great, an area of several hundred square miles of sand or mud may be laid bare in one bay at low-water.

The height of the tide varies from zero up to 60 or 70 feet. It is greatest where, from the form of the land, the tidal wave is cooped up within a narrow inlet or estuary. Under such circumstances the advancing tide sometimes gathers itself into one or more large waves, and rushes furiously up between the converging shores. This is the origin of the "bore" of the Severn, which rises to a height of 9 feet, while the rise and fall of the tide there amounts to 40 feet. In like manner the tides which enter the Bay of Fundy, between Nova Scotia and New Brunswick, get more and more cooped up as they ascend that strait, till they reach a height of 70 feet.

While the tidal swelling is increased in height by the shallowness and convergence of the shores, it gains at the same time force and rapidity. No longer a mere oscillation or pulsation of the great ocean, the tide acquires a true movement of translation, and gives rise to currents which rush past headlands and through narrows in powerful currents and eddies. The rocky and intricate navigation of the west of Scotland and Scandinavia furnishes many admirable illustrations of the rapidity of these tidal currents. The famous whirlpool of Corryreckan, the lurking eddies in the Kyles of Skye, the breakers at the Bore of Duncansbay, and the tumultuous sideway, grimly named by the northern fishermen the Merry Men of Mey, in the Pentland Firth, bear witness to the strength of these sea rivers. At the last-mentioned strait the current at its strongest runs at the rate of 10 miles an hour, which is fully three times the speed of most of our larger rivers.

2. *Currents*.—Recent researches in ocean temperature have disclosed the remarkable fact that beneath the surface layer of water affected by the temperature of the latitude there lies a vast mass of cold water, the bottom temperature of every ocean in free communication with the poles being little above and sometimes actually below the freezing point of fresh water. In the North Atlantic a temperature of 40° Fahr. is reached at an average depth of about 800 fathoms, all beneath that depth being progressively colder.

In the equatorial parts of the same ocean the same temperature comes to within 300 fathoms of the surface. In the South Atlantic, off Cape of Good Hope, the mass of cold water (below 40°) comes likewise to about 300 fathoms from the surface. This distribution of temperature proves that there must be a transference of cold polar water towards the equator, for in the first place the temperature of the great mass of the ocean is much lower than that which is normal to each latitude, and in the second place it is lower than that of the superficial parts of the earth's crust underneath. On the other hand, the movement of water from the poles to the equator requires a return movement of compensation from the equator to the poles, and this must take place in the superficial strata of the ocean. Apart therefore from those rapid river-like streams which traverse the ocean, and to which the name of currents is given, there must be a general drift of warm surface water towards the poles. This is doubtless most markedly the case in the North Atlantic, where besides the current of the Gulf-stream there is a prevalent set of the surface waters towards the north-east. As the distribution of life over the globe is everywhere so dependent upon temperature, it becomes of the highest interest to know that a truly arctic submarine climate exists everywhere in the deeper parts of the sea. With such uniformity of temperature we may anticipate that the abyssal fauna will be found to possess a corresponding sameness of character, and that arctic types may be met with even on the ocean-bed at the equator.

But besides this general drift or set, a leading part in oceanic circulation is taken by the more defined streams termed currents. The tidal wave only becomes one of translation as it passes into shallow water, and is thus of but local consequence. But a vast body of water, known as the Equatorial Current, moves in a general westerly direction round the globe. Owing to the way in which the continents cross its path, this current is subject to considerable deflexions. Thus that portion which crosses the Atlantic from the African side strikes against the mass of South America and divides, one portion turning towards the south and skirting the shores of Brazil, the other bending north-westward into the Gulf of Mexico, and issuing thence as the well-known Gulf-stream. This equatorial water is comparatively warm and light. At the same time the heavier and colder polar water moves towards the equator, sometimes in surface currents like those which skirt the eastern and western shores of Greenland, but more generally as a cold under-current which creeps over the floor of the ocean even as far as the equator.

Much discussion has arisen in recent years as to the cause of oceanic circulation. Two rival theories have been given. According to one of these the circulation entirely arises from that of the air. The trade-winds blowing from either side of the equator drive the water before them until the north-east and south-east currents unite in equatorial latitudes into one broad westerly-flowing current. Owing to the form of the land portions of this main current are deflected into temperate latitudes, and, as a consequence, portions of the polar water require to move towards the equator to restore the equilibrium. According to the other view the currents arise from differences of temperature (and according to some, of salinity also); the warm and light equatorial water is believed to stand at a higher level than the colder and heavier polar water; the former, therefore, flows down as it were polewards, while the latter moves as a bottom inflow towards the equator; the cold bottom water under the tropics is constantly ascending to the surface, whence, after being heated, it drifts away towards the pole, and on being cooled down there, descends and begins another journey to the equator. There can be no doubt that the winds are directly the cause of such currents as

the Gulf-stream, and therefore, indirectly, of return cold currents from the polar regions. It seems hardly less certain that, to some extent at least, differences of temperature, and therefore of density, must occasion movements in the mass of the oceanic waters. The discussion of this subject, however, belongs to another part of this work.¹ The main facts for the geological reader to grasp are—that a system of circulation exists in the ocean, that warm currents move round the equatorial regions, and are tuned now to the one side now to the other by the form of the continents along and round which they sweep; that cold currents set in from poles to equator; and that, apart from actual currents, there appears to be an extremely slow "creep" of the polar water under the warmer upper layers towards the equator.

3. *Waves and Ground-Swell.*—A gentle breeze curls into ripples the surface of water over which it blows. A strong gale or furious storm raises the surface into waves. The agitation of the water in a storm is prolonged to a great distance beyond the area of the original disturbance, and then takes the form of the long heaving undulations termed ground-swell. Waves which break upon the land are called breakers, and the same name is applied to the ground-swell as it bursts into foam and spray upon the rocks. The concussion of earthquakes sometimes gives rise to very disastrous earthquake-waves, as already explained.

The height and force of waves depend upon the breadth and depth of sea over which the wind has driven them, and the form and direction of the coast-line. The longer the "fetch," and the deeper the water, the higher the waves. A coast directly facing the prevalent wind will have larger waves than a neighbouring shore which presents itself at an angle to this wind or bends round so as to form a lee-shore. The highest waves in the narrow British seas probably never exceed 15 or 20 feet, and usually fall short of that amount. The greatest height observed by Dr Scoresby among the Atlantic waves was 43 feet.²

Ground-swell propagated across a broad and deep ocean produces by far the most imposing breakers. So long as the water remains deep and no wind blows, the only trace of the passing ground-swell on the open sea is the huge broad heaving of the surface. But when the water shallows, the superficial part of the swell travelling faster than the bottom begins to curl and crest as a huge billow or wall of water, which finally bursts with enormous force against the shore. Such billows, even when no wind is blowing, often cover the cliffs of the north of Scotland with sheets of water and foam up to heights of 100 or even nearly 200 feet. At Dunnet Head during north-westerly gales the windows of the lighthouse, at a height of upwards of 300 feet above high-water mark, are said to be sometimes broken by stones swept up the cliffs by the sheets of sea water which then deluge the building.

A single roller of the ground-swell 20 feet high falls, according to Mr Scott Russell, with a pressure of about a ton on every square foot. Mr Thomas Stevenson conducted some years ago a series of experiments on the force of the breakers on the Atlantic and North Sea coasts of Britain. The average force in summer was found in the Atlantic to be 611 lb per square foot, while in winter it was 2036 lb, or more than three times as great. But on several occasions, both in the Atlantic and North Sea, the winter breakers were found to exert a pressure of three tons per

square foot, and at Dunbar as much as three tons and a half.³ Besides the waves produced by ordinary wind action, others of an extraordinary size and destructive power are occasionally caused by a violent cyclone-storm. The mere diminution of atmospheric pressure in a cyclone must tend to raise the level of the ocean within the cyclone limits. But the further furious spiral in-rushing of the air towards the centre of the low pressure area drives the sea onward, and gives rise to a wave or succession of waves having great destructive power. Thus, on 5th October 1864, during a great cyclone which passed over Calcutta, the sea rose in some places 24 feet, and swept everything before it with irresistible force, drowning upwards of 48,000 people.

4. *Ice on the Sea.*—In this place may be most conveniently noticed the origin and movements of the ice which in circumpolar latitudes covers the sea. This ice is derived from two sources—(1) the freezing of the sea itself, and (2) the seaward prolongation of land-ice.

1. Three chief types of sea-ice have been observed (*a*) in the Arctic sounds and bays the littoral waters freeze along the shores and form a cake of ice which, upborne by the tide and adhering to the land, is thickened by successive additions below, as well as by snow above, until it forms a shelf of ice 120 to 130 feet broad and 20 or 30 feet high. This shelf, known as the ice-foot, serves as a platform on which the abundant debris loosened by the severe frosts of an arctic winter gathers at the foot of the cliffs. It is more or less completely broken up in summer, but forms again with the early frosts of the ensuing autumn. (*b*) The surface of the open sea likewise freezes over into a continuous solid sheet which in summer breaks up into separate masses sometimes of large extent. This is what navigators term *flake-ice*, and the separate floating cakes are known as *floes*. Ships fixed among these floes have been drifted with the ice for hundreds of miles until at last liberated by its disruption. (*c*) In the Baltic Sea, off the coast of Labrador and elsewhere, ice has been observed to form on the sea-bottom. It is known as ground-ice or anchor ice. In the Labrador fishing-grounds it forms even at considerable depths. Seals caught in the lines at those depths are brought up sometimes solidly frozen.

2. In the Arctic regions the vast glaciers which drain the snow-fields and descend to the sea extend for some distance from the land until large fragments break off and float away seawards. These detached masses are icebergs. Their shape and size greatly vary, but lofty peaked forms are common, and they sometimes rise from 200 to 300 feet above the level of the sea. As only about a ninth part of the ice appears above water, these larger bergs must sometimes be from 2000 to 3000 feet thick from base to top. They consequently require water of some depth to float them, but they are often seen aground. In the Antarctic regions, where one vast sheet of ice envelops the land and extends into the sea as a high rampart of ice, the detached icebergs often reach a great size, and are characterized by the frequency of a flat tabular form.

II. GEOLOGICAL WORK OF THE SEA.

I. *INFLUENCE ON CLIMATE.*—Were there no agencies in nature for distributing temperature, there would be a regular and uniform diminution in the mean annual temperature from equator to poles, and the *isothermal* lines, or lines of equal heat, would coincide with lines of latitude. But no such general correspondence actually exists. If we look at a chart of the globe with the isothermal lines drawn across it, we shall find that their divergences from the parallels are striking, and most so where they approach and cross the ocean. Currents from warm regions raise the

temperature of the tracts into which they flow those from cold regions lower it. The ocean, in short, is the great distributor of temperature over the globe. As an illustration the two opposite sides of the Atlantic may be taken. The cold arctic current flowing southward along the north-east coast of America reduces the mean annual temperature of that region. On the other hand, the Gulf-stream brings to the shores of the north-west of Europe a temperature much above what they would otherwise enjoy. Dublin and the south-eastern headlands of Labrador, lie in the same parallel of latitude, yet differ as much as 18° in their mean annual temperature, that of Dublin being 50°, and that of Labrador 32° Fahr. Dr Croll has calculated that the Gulf-stream conveys nearly half as much heat from the tropics as is received from the sun by the entire Arctic regions.¹

II. EROSION.—The chemical action of the sea upon the rocks of its bed and shores has not yet been properly studied.² It is evident, however, that changes analogous to those effected by fresh water on the land must be in progress. Oxidation, and the formation of carbonates, no doubt continually take place. We may judge indeed of the nature and rapidity of some of these changes by watching the decay of stones and material employed in the construction of piers. At the Bell Rock lighthouse, twenty-five different kinds and combinations of iron were exposed to the action of the sea, and all yielded to corrosion. Mr Mallet—as the result of experiments with specimens sunk in the sea—concluded that from $\frac{1}{10}$ ths to $\frac{1}{5}$ ths of an inch in depth in iron castings 1 inch thick, and about $\frac{1}{10}$ ths of an inch of wrought iron, will be destroyed in a century in clear salt water. Mr Stevenson, in referring to these experiments, remarks that he has in his possession specimens of iron which show even a more rapid rate of decay. In castings used at the Bell Rock the loss has been at the rate of an inch in a century. “One of the bars which was free from air holes had its specific gravity reduced to 5.63, and its transverse strength from 7409 to 4797 lb, and yet presented no external appearance of decay. Another apparently sound specimen was reduced in strength from 4068 lb to 2352 lb, having lost nearly half its strength in fifty years.”³ Similar results were recently observed by Mr Grothe, resident engineer at the railway bridge across the Firth of Tay. A cast-iron cylinder which had been below water for only sixteen months was found to be so corroded that a penknife could be stuck through it in many places.

An examination of the shore will sometimes reveal a good deal of quiet chemical change on the outer crust of rocks exposed to the waves. Such rocks as basalt have their felspar decomposed, and show the presence of carbonates by effervescing briskly with acid. One of these minerals, augite, is occasionally replaced by *pseudomorphs* of carbonate of iron.

It is mainly by its mechanical action that the sea accomplishes its erosive work. This can only take place where the water is in motion, and other things being equal, is greatest where the motion is strongest. Hence we cannot suppose that erosion to any appreciable extent can be effected in the abysses of the sea, where the only motion possible is that slow creeping of the polar water along the bottom already referred to. But where the currents are powerful enough to move grains of sand and gravel,

very slow erosion may take place even at considerable depths. It is in the upper portions of the sea, however, where, owing to currents, tides, and waves, the water suffers most disturbance, that the main mechanical erosion goes on. The depth to which the influence of waves and ground-swell may extend seems to vary greatly according to the situation. The astronomer-royal states that ground-swell may break in 100 fathoms water.⁴ It is common to find boulders and shingle disturbed at a depth of 10 fathoms, and even driven from that depth to the shore, and waves may be noticed to become muddy from the working up of the silt at the bottom when they have reached water of 7 or 8 fathoms in depth.⁵ Gentle movement of the bottom water is said to be sometimes indicated by ripple-marks on the fine sand of the sea-floor at a depth of 600 feet. A good test for the absence of serious abrasion is furnished by the presence of fine mud on the bottom. Wherever that is found, we may be tolerably sure that the bottom at that place lies beyond the reach of ordinary breaker action.⁶ From the upper limit at which the accumulation of mud is possible to high-water mark, and in exposed places up to 100 feet or more above high-water mark, lies the zone within which the sea does its work of abrasion. To this zone, even where the breakers are heaviest, a greater extreme vertical range can hardly be assigned than 300 feet, and in most cases it probably falls far short of that extent.

The mechanical work of erosion by the sea is done in four ways:—(1) the enormous force of the breakers suffices to tear off fragments of the solid rocks; (2) the alternate compression and expansion of the air in the crevices of rocks exposed to heavy breakers dislocates rocks even above the limits of wave-action; (3) the hydraulic pressure of those portions of large waves which enter fissures and cavities forces asunder masses of rock; (4) the waves make use of the loose fragments within their reach in battering down the cliffs exposed to their fury.

(1) Abundant examples of the dislodgement of huge blocks of rock from their parent masses are furnished by the precipitous shores of Caithness, and of the Orkney and Shetland Islands. It sometimes happens that demonstra-

tion of the height to which the effective force of breakers may reach is furnished at lighthouses built on exposed parts of the coast. Thus, at Uist, a door was broken open at a height of 195 feet above the sea, and at the Bishop Rock lighthouse a bell was wrenched off at a level of 100 feet above high-water mark.⁷ Some of the most remarkable instances of the power of breakers have been observed by Mr Thomas Stevenson among the islands of the Shetland group. On the Bound Skerry he found that blocks of rock up to 9½ tons in weight had been washed together at a height of nearly 60 feet above the sea, that blocks weighing from 6 to 13½ tons had been actually quarried out of their original bed, at a height of from 70 to 75 feet, and that a

block of nearly 8 tons had been driven before the waves at the level of 20 feet above the sea, over very rough ground, to a distance of 73 feet (figs. 7 and 8). He likewise records the moving of a 50-ton block by the waves at Baitalshad, in the Hebrides.¹ At Plymouth also, blocks of several tons in weight have been known to be washed about the breakwater like pebbles.²

(2) But, besides their mechanical force, waves acquire a singular and most effective aid from the air. It is a fact familiar to engineers that, even from a vertical and apparently perfectly solid wall of well-built masonry exposed to heavy seas, stones will sometimes be started out of their places, and that when this happens a rapid enlargement of the cavity may be effected, as if the walls were breached by a severe bombardment. At the Eddystone lighthouse, during a storm in 1840, a door which had been securely fastened against the force of the surf from without, was actually driven outward by a pressure acting from within the tower, in spite of the strong bolts and hinges, which were broken. We may infer that, by the sudden sinking of a mass of water hurled against the building, a partial vacuum was formed, and that the air inside forced out the door in its efforts to restore the equilibrium.³ This explanation may partly account for the way in which the stones are started from their places in a solidly built sea-wall. But besides this cause we must also consider a perhaps still more effective one in the condensation of the air driven before the wave between the joints and crevices of the stones, and its subsequent instantaneous expansion when the wave drops. During gales when large waves are driven to shore, many tons of water are poured suddenly into each cleft and cavern within reach. These volumes of water, as they rush in, compress the air into every joint and pore of the rock at the further end, and then quickly retiring, exert such a suction as from time to time to bring down part of the walls or roof. The sea may thus gradually form an inland passage for itself to the surface above, in a "blow-hole" or "putting-hole," through which spouts of foam and spray are in storms shot high into the air. On the more exposed portions of the west coast of Ireland numerous examples of such blow-holes occur. In Scotland, likewise, they may often be observed, as in the Bullers (boilers) of Buchan on the coast of Aberdeenshire, and the Geary Pot near Arbroath. Magnificent instances occur among the Orkney and Shetland Islands, some of the more shattered rocks of these northern coasts being, as it were, honeycombed by sea-tunnels, many of which open up into the middle of fields or moors.

(3) The sea-water which, as part of an inrushing wave, fills the gullies and chinks of the shore-rocks exerts the same pressure upon the walls between which it is confined as the rest of the wave is doing upon the face of the cliff. Each cleft so circumstanced becomes a kind of hydraulic press, the potency of which is to be measured by the force with which the waves fall upon the rocks outside—a force which often amounts to three tons on the square foot. There can be little doubt that by this means considerable pieces of a cliff are from time to time dislodged.

¹ Stevenson, *op. cit.*, pp. 21–27.

² The reader will bear in mind that the specific gravity of bodies is greatly reduced when in water, and still more in sea-water. The following examples will illustrate this fact (Stevenson on *Harbours*, p. 107) —

	Spec. Grav.	No. of cub. feet to a ton in air	No. of feet to 1 in in sea water of sp. grav. 1.028
Basalt	2.90	11.9	18.20
Red granite	2.71	13.2	21.30
Sandstone	2.41	14.8	26.00
Cannel coal	1.01	23.3	70.00

³ Walker, *Proc. Inst. Civ. Engin.*, 15; Stevenson's *Harbours*, p. 10.

(4) But probably of far the largest amount of erosion accomplished by the sea is due not to its own direct mechanical impetus, but to the blows dealt by the boulders, gravel, or sand which it hurls against the shores. This action was aptly compared by Playfair to a kind of artillery.⁴ During a storm upon a shingly coast we may hear, at a distance of several miles, the grind of the stones against each other, as they are dragged back by the recoil of the waves which had launched them forward. In this tear and wear the loose stones are ground smaller, and acquire the smooth round form so characteristic of a surf-beaten beach. At the same time they bruise and wear down the solid cliffs against which they may be driven. Wherever the rock is much jointed, or from any cause presents less resistance to attack, it is excavated into gullies, creeks, and caves, its harder parts standing out as promontories are pierced; gradually a series of detached buttresses and sea stacks appears as the cliff recedes, and these in turn are wasted until they become mere skeries and sunken surf-beaten reefs. Of this progress of destruction the more exposed parts of the British coast-line furnish many admirable examples. The west coast of Ireland, exposed to the full swell of the Atlantic, is in innumerable localities completely undermined by caverns, into which the sea enters from both sides. In many places the cliffs are as vertical as walls, this feature depending upon their joints, which enable slices after slices to be undermined and removed. The precipitous coasts of Skye, Sutherland, Caithness, Forfar, Kincardine, and Aberdeenshire abound in the most impressive lessons of the waste of a rocky sea-margin; while the same picturesque features are prolonged into the Orkney and Shetland Islands, the magnificent cliffs of Hoy towering as a vast wall some 1200 feet above the Atlantic breakers, which are tunnelling and fretting their base.

If such is the progress of waste where the materials consist of the most solid rocks, we may expect to meet with at least equally impressive proofs of decay where the coast-line can oppose only soft sand or clay to the march of the breakers. Again, the geological student in Britain can examine for himself many illustrations of this kind of destruction around the shores of these islands. Within the last few hundred years entire parishes with their towns and villages have been washed away, and the tide now ebbs and flows over districts which in old times were cultivated fields and cheerful hamlets. The coast of Yorkshire between Flamborough Head and the mouth of the Humber, and also that between the Wash and the mouth of the Thames, suffer at a specially rapid rate, for the cliffs in these parts consist in great measure of soft clay. In some places this loss is said to amount to 3 feet per annum.

While investigating the proofs of decay along the shore, the geologist endeavours to ascertain to what extent the action of the waves is assisted by that of rain, springs, frosts, and general atmospheric disintegration. He often finds that the progress of the waves depends not so much upon their own labours as upon those of the terrestrial agencies already described. A crumbling cliff, battered and wasted by the breakers, will yield to him abundant evidence of the manner in which the other agents of destruction prepare the way for its final demolition and removal by the sea, and he will learn that the very blocks of stone which give the waves so much of their efficacy are in great measure furnished to them by these co-operating agents. If the cutting back of a cliff were mainly the work of the sea, we ought to find the cliff overhanging, because the sea acts only at its base. But the fact that in the vast majority of cases sea-cliffs, instead of overhanging, slope backward, at a greater or less angle, from the sea, shows that the waste from subaerial action is

⁴ Illustrations of the Huttonian Theory, sec. 97.

really greater than that from the action of the breakers. What the sea chiefly does is to break down and wash away the rubbish that falls from the cliffs, and thus to leave an ever fresh surface for renewed denudation.

(5.) Among the erosive operations of the sea must be included what is performed by floating ice. Along the margin of arctic lands a good deal of work is done by the broken up floe-ice and ice-foot. These cakes of ice, driven ashore by storms, tear up the soft shallow-water or littoral deposits, rub and scratch the rocks, and push gravel and blocks of rock before them as they strand on the beach. Icebergs also, when they get aground in deep water, must greatly disturb the sediment accumulating there, and must grind down any submarine rock on which they grate as they are driven along.

The general result of the erosive action of the sea on the land is the production of a submarine plain. As the sea advances by cutting slice after slice away from the coast, successive lines of beach pass under low-water mark. The whole of the littoral belt, as far down as wave action has influence, is continually being ground down by the moving detritus. If no change of level between sea and land should take place, the sea might conceivably eat its way slowly far into the land, and produce a gently sloping yet almost horizontal selvaige of plain covered permanently by the waves. In such a submarine plain the influence of geological structure, and notably of the relative powers of resistance of different rocks, would make itself conspicuous. The present promontories caused by the superior hardness of their component rocks would no doubt be represented by ridges on the subaqueous plateau, while the existing bays and creeks worn out of softer rocks would be marked by lines of valleys or hollows.

III. TRANSPORT.—The sea by means of its surface-drifts and currents carries sedimentary material to great distances and strews them over its floor. Near land, where the movements of the water are active, much coarse detritus is transported along shore or swept farther out to sea. A prevalent wind, by creating a current in a given direction along a coast-line, will cause the shingle to travel coast-wise, the stones getting more and more rounded and reduced in size as they recede from their sources. The Chesil Bank, which runs as a natural breakwater 16 miles long connecting the Isle of Portland with the mainland of Dorsetshire, consists of rounded shingle which is constantly being driven westwards. On the Moray Firth the reefs of quartz-rock about Cullen furnish abundance of shingle, which moves westwards along the coast for more than 15 miles. The coarser sediment probably seldom goes much beyond the littoral zone. Fine gravel, however, is pushed along the bottom by currents even at 600 fathoms; for at that depth in the North Atlantic between the Faroe Islands and Scotland small pebbles of volcanic and other rocks are dredged up which have probably been carried by an arctic under-current from the north. At greater depths the force of currents at the bottom must be too feeble to push along any detritus. But much fine sediment is carried in suspension by the sea for long distances from land. Some rivers, as the Amazon, pour so much silt into the sea as to discolour its water for several hundred miles away from land. After wet weather the coast-waters round the shores of the British Islands are sometimes made turbid from the quantity of mud brought down from the land. Dr Carpenter found the bottom waters of the Mediterranean to be everywhere permeated by an extremely fine mud, derived no doubt from the rivers and shores of that sea, borne away out far from land, and settling slowly down upon the bottom. He remarks that the characteristic blueness of the Mediterranean may be explained, like that of the Lake of Geneva (as shown by Dr

Tyndall), by the diffusion of those exceedingly minute sedimentary particles through the water.

But the most startling evidence of the wide extent to which transport takes place in the ocean is that supplied by the observations made during the voyage of the "Challenger." From the abysses of the Pacific Ocean, at the furthest distances from land, the dredge brought up bushels of rounded pieces of pumice of all sizes up to blocks a foot in diameter. These fragments were all evidently water-worn, and almost certainly were derived from the land. Some small pieces indeed were taken on the surface in the tow-net. Round volcanic islands, and off the coasts of volcanic tracts of the mainland, the sea is sometimes covered with floating pieces of water-worn pumice swept out by flooded rivers. These fragments drift away for hundreds or even thousands of miles until, becoming water-logged, they sink to the bottom. Their universal distribution was one of the most noticeable features in the dredgings of the "Challenger." The clay which is found on the bottom of the ocean at the greatest distances from any shore may be partly due to its transport in that condition from land, but more probably to the decomposition of the drifted pumice.¹

Another not unimportant process of marine transport is that performed by floating ice. Among the arctic glaciers moraine stuff is of rare occurrence; but occasional blocks of rock and heaps of earth and stones fall from the cliffs which rise above the general waste of snow. Hence on the icebergs that float off from these glaciers, rock debris sometimes may be observed. It is transported southward for hundreds of miles until, by the shifting or melting of the bergs, it is dropped into deep water. The floor of certain portions of the North Atlantic in the pathway of the bergs must be plentifully strewn with this kind of detritus. By means of the ice-foot also, an enormous quantity of earth and stones is every year borne away from the shore as the ice breaks up, and strewn over the floor of the sounds, bays, and channels.

IV. REPRODUCTION.—The sea being the receptacle for the material worn away from the land must receive and store up in its depths all that vast amount of detritus by the removal of which the level and contours of the land are in the course of time so greatly changed. The deposits which take place within the area covered by the sea may be divided into two groups—the inorganic and organic. It is the former with which we have at present to deal; the latter will be discussed with the other geological functions of plants and animals. The inorganic deposits of the sea-floor are partly (a) land-derived or terrigenous, partly (b) abyssal.

(a.) *Land-derived or Terrigenous.*—These may be conveniently grouped according to their relative places on the sea-bed.

(1.) *Shore Deposits.*—The most conspicuous and familiar are the layers of gravel and sand which accumulate between tide-marks. As a rule, the coarse materials are thrown up about the upper limit of the beach. They seem to remain stationary there; but if watched and examined from time to time, they will be found to be continually shifted by high tides and storms, so that the bank or bar of shingle retains its place though its component pebbles are being constantly moved. Below the limit of coarse shingle upon the beach lies the zone of fine gravel, and then that of sand. These zones are far from being constant; yet when they all occur on the same beach, they tend to range themselves according to their relative coarseness, the rougher detritus lying at the upper, and the finer towards the lower edge of the shore. The nature of the littoral accumulations on any

¹ Murray, *Proc. Roy. Soc. Edin.*, 1876-7, p. 247.

given part of a coast-line must depend either upon the character of the shore-rocks which at that locality are broken up by the waves, or upon the set of the shore-currents and the kind of detritus they bear with them. Coasts exposed to heavy surf, especially where of a rocky character, are apt to present beaches of coarse shingle between their projecting promontories. Sheltered bays, on the other hand, where wave action is comparatively feeble, afford a gathering ground for fine sediment such as sand and mud. Estuaries and inlets into which rivers enter frequently show wide muddy flats at low water. The mud brought down by the fresh water is allowed to sink to the bottom when the motion of the current is checked as it enters the sea.

(2.) *Infra-Littoral and Deep-sea Water Deposits.*—These extend from below low-water mark to a depth of sometimes as much as 2000 fathoms, and reach a distance from land varying up to 200 miles or even more. Near land, and in comparatively shallow water, they consist of banks or sheets of sand more rarely mixed with gravel. The bottom of the North Sea, for example, which between Britain and the continent of Europe lies at a depth never reaching 100 fathoms, is irregularly marked by long ridges of sand enclosing here and there hollows where mud has been deposited. In the English Channel large banks of gravel extend through the Straits of Dover as far as the entrance to the North Sea. These features seem to indicate the line of the chief mud-bearing streams from the land, and the general disposition of currents and eddies in the sea which covers that region, the gravel ridges marking the tracks of the more rapidly moving currents, while the muddy hollows point to the eddies where the fine sediment is permitted to settle on the bottom. It is possible, however, that the inequalities on the floor of the North Sea, and their peculiarities of sediment, may not be due wholly to modern accumulations, but partly to the contour of the ground before it was submerged and the land connexion between Britain and Europe was destroyed.

During the course of the voyage of the "Challenger," the approach to land could always be foretold from the character of the bottom, even at distances of 150 and 200 miles from land. The deposits were found to consist of blue and green muds derived from the degradation of older crystalline rocks. At depths of 100 to 700 fathoms they are often coloured green by glauconite. At greater depths they consist of blue or dark slate-coloured mud with a thin upper layer of red or brown. Throughout these land-derived sediments particles of mica, quartz, and other minerals are distributed, the materials becoming coarser towards land. Pieces of wood, portions of fruits, and leaves of trees occur in them, and further indicate the reality of the transport of material from the land. Shells of pteropods, larval gastropods, and lamellibranchs are tolerably abundant in these muds, with many *infra-littoral* species of *Foraminifera*, and diatoms. Below 1500 or 1700 fathoms pteropod shells seldom appear, but at 3000 fathoms hardly a foraminifer or any calcareous organism remains (Murray, *Proc. Roy. Soc. Edin.*, 1876, p. 519). Round volcanic islands the bottom is found to be covered with grey mud and sand derived from the degradation of volcanic rocks. These deposits can be traced to great distances, as at Hawaii for 200 miles or more. Pieces of pumice, scoriae, &c., occur in them, mingled with marine organisms, and more particularly with abundant grains, incrustations, and nodules of an earthy peroxide of manganese. Near coral-reefs the sea-floor is coated with a white calcareous mud derived from the abrasion of the coral. The east coast of South America supplies a peculiar red mud which is spread over the Atlantic slope down to depths of more than 2000 fathoms.

(6.) *Abyssal.*—Passing over at present the organic deposits which form so characteristic a feature on the floor

of the deeper and more open parts of the ocean, we come to certain red and grey clays found at depths of more than 2000 fathoms down to the bottoms of the deepest abysses. These consist of exceedingly fine clay, coloured sometimes red by iron-oxide, sometimes of a chocolate tint from manganese oxide, with grains of quartz, mica, punice, scoriae, peroxide of manganese, and other mineral substances, together with *Foraminifera*, and in some regions a large proportion of siliceous *Radiolaria*. Mr Murray has shown the high probability that these clays result from the decomposition of pumice and fine volcanic dust transported from volcanic islands into mid-ocean. The extreme slowness of their deposit is strikingly brought out in the tracts farthest removed from land. From these localities great numbers of sharks' teeth, with ear-bones and other bones of whales, were dredged up in the "Challenger" expedition,—some of them quite fresh, others partially crusted with peroxide of manganese, and some completely and thickly surrounded by that substance. We cannot suppose that sharks and whales so abundant in the sea as to cover the floor of the ocean with a continuous stratum of their remains. No doubt each haul of the dredge which brought up so many bones represented the droppings of many generations. The successive stages of manganese incrustation point to a long, slow, undisturbed period, when so little sediment accumulated that the bones dropped at the beginning remained at the end still uncovered, or only so slightly covered as to be easily scraped up by the dredge. In these deposits, moreover, Mr Murray has found numerous minute spherular particles of metallic iron which there is every reason to believe are of cosmic origin—portions of the dust of meteorites which in the course of ages have fallen upon the sea-bottom. Such particles no doubt fall all over the ocean; but it is only on those parts of the bottom which, by their distance from any land, receive accessions of deposit with extreme slowness, and where therefore the present surface may contain the dust of a long succession of years, that it has been possible to detect them.

The abundant deposit of peroxide of manganese over the floor of the deep sea is one of the most singular features of recent discovery. It occurs as an earthy incrustation round bits of pumice, bones, and other objects. The nodules possess a concentric arrangement of lines not unlike those of urinary calculi. That they are formed on the spot, and not drifted from a distance, was made abundantly clear from their containing abyssal organisms, and enclosing more or less of the surrounding bottom, whatever its nature might happen to be. Mr Murray refers their origin to the decomposition of the manganese-bearing minerals in the universally diffused volcanic detritus. Quite recently Mr J. Y. Buchanan has dredged similar manganese concretions from some of the deeper parts of Loch Fyne. In connexion with the chemical reactions indicated by these nodules as taking place on the sea-bottom, reference may be made to a still more remarkable but yet unpublished discovery made by Mr Murray in the course of his examinations of the materials brought up from the same abyssal deposits. He has detected abundant minute concretions or bundles of crystals which on analysis are found to resemble olivine in composition. These silicates (there may be several of them) have certainly been formed directly on the sea-bottom, for they are found gathered round abyssal organisms. It is difficult to overestimate the importance of this fact in reference to the chemistry of marine deposits.

From a comparison of the results of the dredgings made in recent years in all parts of the oceans, it is impossible to resist the conclusion that there is nothing in the character of the deep-sea deposits which finds a parallel among the marine geological formations visible to us on the land. It is only among the comparatively shallow water accumulations

of the existing sea that we encounter analogies to the older formations. And thus we reach by another and a new approach the conclusion which on very different grounds has been arrived at, viz., that the present continental ridges have existed from the remotest times, and that the marine strata which constitute so large a portion of their mass have been accumulated not as deep water formations, but in comparatively shallow water along their flanks.

Section III—Life

Among the agents by which geological changes are carried on upon the surface of the globe living organisms must be enumerated. Both plants and animals co-operate with the inorganic agents in promoting the degradation of the land, and in some cases, on the other hand, they protect rocks from decay. Again by the accumulation of their remains they form extensive formations both upon the land and in the sea. Their operations may hence be described as alike destructive, conservative, and reproductive. Under this heading also we may notice the influence of man as a geological agent.

I. DESTRUCTIVE ACTION.—Plants aid in the general progress of disintegration in various ways. 1. By keeping the surfaces of rocks moist, and thus promoting both the mechanical and chemical dissolution of the rocks. This action is especially shown by liverworts, mosses, and other plants which only thrive in copious moisture. 2. By producing through their decay carbonic and other acids, which, with decaying organic matter taken up by passing moisture, become potent in effecting the chemical decomposition of rocks, and in promoting the disintegration of soils. 3. By inserting their roots or branches between joints of rock, which are thereby loosened, so that large slices may be eventually wedged off. On the sides of wooded hills and cliffs this process may often be seen; even among old ruins an occasional sapling ash or elm may be found to have cast its roots round a portion of the masonry and to be slowly detaching it from the rest of the wall. 4. By attracting rain, as thick woods, forests, and mosses do, and thus accelerating the general scouring of a country by running water. The indiscriminate destruction of the woods in the Levant has been assigned with much plausibility as the main cause of the present desiccation of that region. 5. By promoting the decay of diseased and dead plants and animals, as when fungi over-spread a damp rotting tree or the carcass of a dead animal.

Of the destructive influences of animal life numerous illustrations might be given. 1. The composition and arrangement of soil are affected. Worms are continually engaged in bringing up the lower portions of the soil to the surface, and thus increase its fertility and its capability of being washed away by rain. Burrowing animals, by throwing up the soil and subsoil, expose these to be dried and blown away by the wind. At the same time their subterranean passages serve to drain off the superficial water and to injure the stability of the surface of the ground above them. In Britain the mole and rabbit are familiar examples. In North America the prairie dog has undermined extensive tracts of pasture land in the west. In Cape Colony wide areas of open country seem to be in a constant state of eruption from the burrowing operations of multitudes of *Bathyerges* and *Chrysochloris*—small mole-like animals which bring up the soil and bury the grassy vegetation under it. 2. The flow of streams is sometimes interfered with, or even diverted, by the operations of animals. Thus the beaver, by constructing dams, checks the current of water-courses, intercepts floating materials, and sometimes even diverts the water into new channels. This action is typically displayed in Canada and other parts of North America. The embankments of the Mississippi are sometimes weakened to such an extent by the burrowings of the

clay-fish as to gave way and allow the river to inundate the surrounding country. Similar results have happened in Europe from the subterranean operations of rats. 3. Some Mollusca (*Pholas*, *Saxicava*, *Teredo*, &c.) bore into stone or wood, and by the number of contiguous perforations greatly weaken the material. Pieces of drift-wood are soon riddled with long holes by the teredo; while wooden piers, and the bottom of wooden ships, are often rapidly perforated. The saxicavous shells, by piercing rocks and leaving open cavities for rain and sea water to fill, promote the decay of the stone. 4. Many animals exercise a ruinously destructive influence upon vegetation. Of the many insect plagues of that kind it will be enough to enumerate the locust, phylloxera, and Colorado beetle. The pasture in some parts of the south of Scotland has in recent years been much damaged by mice, which have increased in numbers owing to the indiscriminate shooting and trapping of owls, hawks, and other predaceous creatures. Grasshoppers cause the destruction of vegetation in some parts of Wyoming and other western territories of the United States. The way in which animals destroy each other, often on a great scale, may likewise be included among the geological operations now under description.

II. CONSERVATIVE ACTION.—This is admirably shown by many kinds of vegetation. 1. The formation of a stratum of turf protects the soil and rocks from being rapidly disintegrated and washed away by atmospheric action. Hence the surface of a district so protected is denuded with extreme slowness except along the lines of its water-courses. 2. Many plants, even without forming a layer of turf, serve by their roots or branches to protect the loose sand or soil on which they grow from being removed by wind. The common sand-carex and other arenaceous plants bind the loose sand-dunes of our coasts, and give them a permanence which would at once be destroyed were the sand laid bare again to storms. In North America the sandy tracts of the western territories are in many places protected by plants known as sage-brush and grease-wood. The growth of shrubs and brushwood along the course of a stream not only keeps the alluvial banks from being so easily undermined and removed as would otherwise be the case, but serves to arrest the sediment in floods, filtering the water, and thereby adding to the height of the flood plain. On some parts of the west coast of France extensive ranges of sand-hills have been gradually planted with pine woods which, while preventing the destructive inland march of the sand, also yield a large revenue in timber, and have so improved the climate as to make these districts a resort for pulmonary invalids. In tropical countries the mangrove grows along the margin of the sea, and not only protects the land, but adds to its breadth, by forming and increasing an alluvial belt along the coast. 3. Some marine plants likewise afford protection to shore rocks. This is done by the calcareous nullipores, which form upon them a hard incrustation; likewise by the tangles and smaller fuci which grow abundantly on the littoral zone and break the force of the waves, or diminish the effects of ground swell. 4. Forests and brushwood protect the soil, especially on slopes, from being washed away by rain. This is shown by the disastrous results of the thoughtless destruction of such woods. According to Reclus (*La Terre*, p. 410), in the three centuries from 1471 to 1776, the "vigueries," or provosty-districts of the French Alps, lost a third, a half, and even three-fourths of their cultivated ground, and the population has diminished in somewhat similar proportions. From 1836 to 1866 the departments of Hautes and Basses Alpes lost 25,000 inhabitants, or nearly one-tenth of their population—a diminution which has with plausibility been assigned to the reckless removal of the pine forests, whereby the steep

mountain sides have been washed bare of their soil. The desecration of the countries bordering the eastern Mediterranean has been ascribed to a similar cause. 5. In mountain districts pine forests exercise also an important conservative function in preventing the formation or arresting the progress of avalanches. In Switzerland some of the forests which cross the lines of frequent snow-falls are carefully preserved.

Animals do not exert any important conservative action upon the earth's surface, save in so far as they form new deposits, as will be immediately referred to. In the prairie regions of Wyoming and other tracts of North America, some interesting minor effects are referable to the herds of roving animals which migrate over these territories. Professor Comstock describes the trails made by the bison, the elk, and the big-horn or mountain-sheep as firmly-trodden tracks on which vegetation will not grow for many years. All over the region traversed by the bison numerous circular patches of grass are to be seen which have been formed on the hollows where this animal has wallowed. Originally they are shallow depressions formed in great numbers where a herd of bisons has rested for a time. On the advent of the rains they become pools of water; thereafter grasses spring up luxuriantly, and so bind the soil together that these grassy patches, or "bison-wallows," may actually become slightly raised above the general level if the surrounding ground becomes parched and degraded by the winds (*Reconnaissance of N.W. Wyoming*, 1875, p. 175).

III. REPRODUCTIVE ACTION.—Both plants and animals contribute materials towards new geological formations. Their remains are enclosed in deposits of sand and mud and there preserved. But they form of themselves not unimportant accumulations. Of plant formations the following illustrative examples may be given. (1.) *Peat-Mosses*.—These are accumulations of marshy vegetation which occur in temperate and arctic latitudes, sometimes to a depth of 40 feet or more. In Europe they have been largely formed by plants of the genus *Sphagnum*, which, growing as a spongy fibrous mass over wet ground, die in their lower parts and send out new fibres above. It is this lower decaying stratum which forms the peat. Every stage of the process may be seen in a large moss, from the green living plants at the top, through fibrous brown turf full of the scarcely decayed rootlets of the *Sphagnum*, down to the compact brown or almost black peat at the bottom. Many peat-mosses were at one time lakes which have been gradually filled up by the accumulation of marsh-plants. Peat possesses a great antiseptic power; the bodies of animals which have been entombed in it are sometimes preserved for many centuries. (2.) *Mangrove Swamps*.—On the low moist shores and river mouths of tropical countries, the mangrove tree plays an important geological part. It grows in such situations in a dense jungle, sometimes 20 miles broad, which fringes the coast as a green sylvage, and runs up if it does not quite occupy creeks and inlets. The mangrove flourishes in sea-water even down to low-water mark, forming there a dense thicket which, as the trees drop their radicles and take root, grows outward into the sea. It is singular to find terrestrial birds nestling in the branches above and crabs and barnacles living among the roots below. By this network of subaqueous radicles and roots the water is filtered of its sediment, which, retained among the vegetation, helps to turn the spongy jungle into a firm soil. On the coast of Florida the mangrove swamps stretch for long distances as a belt from 5 to 20 miles broad, which winds round the creeks and inlets. At Bermuda the mangroves co-operate with grasses and other plants to choke up the creeks and brackish lakes. In these waters calcareous algae abound, and as their remains are thrown up amidst the sand and vegetation they form a remarkably calcareous soil. (3.) *Diatom Mud or Earth*.—As the minute siliceous plants

called diatoms occur both in fresh and salt water, the deposit formed from their congregated remains is found both on the sites of lakes and on the sea-floor. "Infusorial" earth and "triph powder" consist mainly of the frustules and fragmentary debris of diatoms which have accumulated on the bottoms of lacustrine areas. Towards the Antarctic circle the "Challenger" met with *Diatomacea* in abundance, both in the surface waters of the ocean and on the bottom. They form at depths of from 1260 to 1975 fathoms a pale straw-coloured deposit, which when dried is white and very light.

Animal formations are chiefly composed of the remains of the lower grades of the animal kingdom, especially of *Mollusca*, *Actinozoa*, and *Foraminifera*. (1.) In some cases they are *calcareous*. Lime, chiefly in the form of carbonate, is the mineral substance of which the solid parts of animals are mainly built up. Hence the great majority of the accumulations formed of animal remains are calcareous. In fresh water they are represented by the *marl* of lakes—a white, chalky deposit consisting of the mouldering remains of *Mollusca*, *Entomostraca*, and partly of fresh-water algae. On the sea-bottom in shallow water they consist of beds of shells, such as the oyster-banks of English seas. The fringing, barrier, and atoll coral-reefs of warm seas are conspicuous examples of wide and thick masses of rock formed from the accumulated growth of animal organisms. The great reef of Australia, for example, is 1250 miles long, from 10 to 90 miles broad, and more than 1800 feet thick. The coral rock, though formed by the continuous growth of the polyps, gradually loses any distinct organic structure, and acquires an internal crystalline character owing to the infiltration of water through its mass, whereby carbonate of lime is carried down and deposited in the pores and crevices as in a growing stalactite. Great quantities of calcareous mud are produced by the breakers which beat upon the outer edge of the reefs. This mud is partly washed up upon the reefs and aids in their consolidation, but in great measure it is swept away by the ocean currents and distributed over many thousands of square miles of the sea-floor. In deep water over the bed of the Atlantic and other oceans a remarkable calcareous ooze occurs which is formed of the remains of *Foraminifera*, and chiefly of species of the genus *Globigerina*. It is next in abundance to the red and grey clays of the deep sea. It is a pale-grey marl, sometimes red from peroxide of iron, or brown from peroxide of manganese; and it usually contains more or less clay, even with occasional fragments of pumice. (2.) *Siliceous* deposits formed from animal exuvium are illustrated by another of the deep-sea formations brought to light by the "Challenger" researches. In certain regions of the western and middle Pacific Ocean, the bottom was found to be covered with an ooze consisting almost entirely of *Radiolaria*. These minute organisms occur, indeed, more or less abundantly in almost all deep oceanic deposits. From the deepest sounding yet taken (4575 fathoms, or more than 5 miles) a radiolarian ooze was obtained. The spicules of sponges likewise furnish materials towards these siliceous accumulations. (3.) *Phosphate* deposits, in the great majority of cases, betoken some of the vertebrate animals, seeing that phosphate of lime enters largely into the composition of their bones and occurs in their excrement. The most typical modern accumulations of this nature are the guano beds of rainless islands off the western coasts of South America and Southern Africa. In these regions immense flocks of sea-fowl live in the course of centuries covered the ground with an accumulation of their droppings to a depth of sometimes 30 to 80 feet, or even more. This deposit, consisting chiefly of organic matter and ammoniacal salts, with about 20 per cent. of phosphate of lime, has acquired a high value as a manure, and is being rapidly cleared off. It could only have been

preserved in a rainless or almost rainless climate. On the west of Europe isolated stacks and rocky islands in the sea are often seen to be white from the droppings of clouds of sea birds, but it is merely a thin crust, which is not allowed to grow thicker in a climate where rains are frequent and heavy.

IV. MAN AS A GEOLOGICAL AGENT.—No survey of the geological workings of plant and animal life upon the surface of the globe can be complete which does not take account of the influence of man—an influence of enormous and increasing consequence in physical geography, for man has introduced, as it were, an element of antagonism to nature. Not content with gathering the fruits and capturing the animals which she has offered for his sustenance, he has, with advancing civilization, engaged in a contest to subdue the earth and possess it. His warfare indeed has often been a blind one, successful for the moment, but leading to sure and sad disaster. He has, for instance, stripped off the woodland from many a region of hill and mountain, gaining his immediate object in the possession of their stores of timber, but thereby laying bare the slopes to parching droughts or fierce rains. Countries once rich in beauty, and plenteous in all that was needful for his support, are now burnt and barren, or washed bare of their soil. It is only in comparatively recent years that he has learnt the truth of the aphorism—"Homo Naturæ minister et interpres."¹

But now, when that truth is coming more and more to be recognized and acted on, man's influence is none the less marked. His object still is to subdue the earth, and he attains it, not by setting nature and her laws at defiance, but by enlisting her in his service. Within the compass of this article it is impossible to give more than merely a reference to this vast subject. The action of man may be witnessed on climate, on the flow of water, on the character of the terrestrial surface, and on the distribution of life.¹

1. *On Climate.*—Human interference affects meteorological conditions.—(1) by removing forests and laying bare to the sun and winds areas which were previously kept cool and damp under trees, or which, lying on the lee side, were protected from tempests, as already stated, it is supposed that the wholesale destruction of the woodlands formerly existing in countries bordering the Mediterranean has been in part the cause of the present desiccation of these districts; (2) by drainage, the effect of this operation being to remove rapidly the discharged rainfall, to lessen the evaporation, and thereby to diminish the rainfall and somewhat increase the general temperature of a country; (3) by the other processes of agriculture, such as the transformation of moor and bog into cultivated land, and the clothing of bare hillsides with green crops or plantations of coniferous and hardwood trees.

2. *On the Flow of Water.*—1. By increasing or diminishing the rainfall man directly affects the course of the waters over the land. 2. By his drainage operations he makes the rain to run off more rapidly than before, and thereby increases the floods in the rivers. 3. By wells, bores, mines, or other subterranean works he interferes with the underground waters and consequently with the discharge of springs. 4. By embanking rivers he confines them to narrow channels, sometimes increasing their scour, and enabling them to carry their sediment further seaward, sometimes causing them to deposit it over the plains and raise their level.

3. *On the Surface of the Land.*—Man's operations alter

¹ The reader will find much suggestive matter in Marsh's *Man and Nature*, a work which, as its title denotes, specially treats of this subject. A new and enlarged edition of this volume was published in 1874 under the title of *The Earth as Modified by Human Action*.

the aspect of a country in many ways:—(1) by changing forest into bare mountain, or clothing bare mountains with forest; (2) by promoting the growth or causing the removal of peat-mosses, (3) by heedlessly uncovering sand-dunes, and thereby setting in motion a process of destruction which may convert hundreds of acres of fertile land into waste sand, or by prudently planting the dunes with sand-loving vegetation or pines, and thus arresting their landward progress; (4) by so guiding the course of rivers as to make them aid him in reclaiming waste land, and bringing it under cultivation; (5) by piers and bulwarks, whereby the ravages of the sea are stayed, or by the thoughtless removal from the beach of stones which the waves had themselves thrown up, and which would have served for a time to protect the land, (6) by forming new deposits either designedly or incidentally. The roads, bridges, canals, railways, tunnels, villages, and towns with which man has covered the surface of the land will in many cases form a permanent record of his presence. Under his hand the whole surface of civilized countries is very slowly covered by a stratum, either formed wholly by him, or due in great measure to his operations, and containing many relics of his presence. The soil of old cities has been increased to a depth of many feet by the rubbish of his buildings; the level of the streets of modern Rome stands high above that of the pavements of the Cæsars, and that again above the roadways of the early republic. Over cultivated fields his potsherds are turned up in abundance by the plough. The loam has risen within the walls of his graveyards, as generation after generation has mouldered there into dust.

4. *On the Distribution of Life.*—It is under this head, perhaps, that the most subtle of human influences come. Some of man's doings in this domain are indeed plain enough, such as the extirpation of wild animals, the diminution or destruction of some forms of vegetation, the introduction of plants and animals useful to himself, and especially the enormous predominance given by him to the cereals and to the spread of sheep and cattle. But no such extensive disturbance of the normal conditions of the distribution of life can take place without carrying with it many secondary effects, and setting in motion a wide cycle of change and of reaction in the animal and vegetable kingdoms. For example, the incessant warfare waged by man against birds and beasts of prey in districts given up to the chase leads sometimes to unforeseen results. The weak game is allowed to live, which would otherwise be killed off and give more room for the healthy remainder. Other animals which feed perhaps on the same materials as the game are by the same cause permitted to live unchecked, and thereby to act as a further hindrance to the spread of the protected species. But the indirect results of man's interference with the régime of plants and animals still require much prolonged observation.

From this brief and imperfect outline the reader may perceive that man takes an important place as a geological agent, and that in future ages the traces of his interference will introduce a new element of difficulty into the study of geological phenomena.

PART IV.—STRUCTURAL GEOLOGY,

OR THE ARCHITECTURE OF THE EARTH'S CRUST.

Having considered the nature of the materials constituting the crust of the earth, and the operation of the different agencies by which these materials are produced, arranged, and modified, we may now proceed to examine the structure of the crust itself with the view of marking how its component parts have been put together. Since by far the largest portion of the crust consists of sedimentary or

aqueous rocks, it will be of advantage to treat of them first, noting, in the first place, their original characters as resulting from the circumstances under which they were formed, and afterwards, the modifications subsequently effected upon them. Many of these superinduced structures, which are not peculiar to sedimentary, but occur more or less markedly in all rocks, may be conveniently described together. The distinctive characters of the igneous or eruptive rocks, as portions of the architecture of the crust will then be described; and lastly, those of the crystalline schists and other associated rocks to which the name of metamorphic is usually applied.

I. STRATIFICATION AND ITS ACCOMPANIMENTS.

The term "stratified," so often applied as a general designation to the aqueous or sedimentary rocks, expresses their leading structural feature. They are arranged in layers or strata, an arrangement characteristic of them alike in hand-specimens and in the cliffs of mountains. Not that every morsel of aqueous rock exhibits evidence of stratification. But it is this characteristic which is least frequently absent. The general aspects of stratification will be best followed in an explanation of the terms by which they are expressed.

Laminae are the thinnest paper-like layers of deposit in a stratified rock. Such fine layers only occur where the material is fine-grained, as in mud or shale, or where fine scales of some mineral have been plentifully deposited, as in micaceous sandstone. In some laminated rocks the laminae cohere so firmly that they can hardly be split open, and the rock will break more readily across them than in their direction. More usually, however, the planes of lamination serve as convenient divisional planes by means of which the rock can be split open. The frequency with which laminae can be separated from each other, indicating, as it does, a failure of coherence between the layers of deposit, may probably be taken as a proof that these layers were originally laid down at intervals of sufficient duration to admit of a considerable amount of consolidation of one layer before the deposition of the next. It is quite possible that in many, if not in most cases, these intervals were of longer duration than those required for the successive deposit of the laminae. In estimating therefore the length of time represented by say one foot of such finely laminated rock, we might reasonably regard the actual time occupied in deposition as only a small fraction of the whole interval.

The existence of laminae points to tranquil conditions of slow intermittent deposit. The sediment has been borne at intervals and fallen over the same area of undisturbed water. Regularity of thickness and persistence of lithological character among the laminae may be taken to indicate periodic currents, of approximately equal force, from the same quarter. In some cases successive tides in a sheltered estuary may have been the agent of deposition. In others the sediment was doubtless brought by recurring river-floods. A great thickness of laminated rock, like the massive shales of Palaeozoic formations, points to a prolonged period of quiescence, and probably, in most cases, to slow, tranquil subsidence of the sea-floor. On the other hand, the alternation of thin bands of laminated rock with others coarser in texture and non-laminated suggests considerable oscillation of currents from different quarters bearing different qualities and amounts of sediment.

Strata or *Beds* are layers of rock varying from an inch or less up to many feet in thickness. A stratum may be made up of many laminae, if the nature of the sediment and mode of deposit have favoured the production of this structure. This has very commonly been the case where the sediment

has been exceedingly fine-grained. Where the materials are of coarser grain, the strata, as a rule, are not laminated, but form the thinnest parallel divisions of the mass of rock. Strata, like laminae, may either cohere firmly, or, as more usually happens, be separable with more or less ease from each other. In the former case we may suppose the upper to have followed the lower bed without the lapse of an interval long enough to allow of the consolidation of the latter. The common merging of a stratum into that which overlies it must no doubt be regarded as evidence of more or less gradual change in the conditions of deposit. Where the overlying bed shows no cohesion with that below it, the interval was probably of some duration. A stratum may be one of a series of similar beds in the same mass of rock. Thus a thick sandstone consists of many individual strata, varying it may be very considerably in their respective thicknesses. Or a stratum may be complete and distinct in itself, as where one of limestone or ironstone runs through the heart of a series of shales. As a general rule we may conclude that wherever among sedimentary accumulations stratification is exceedingly well-marked the rocks were formed rather slowly, and that where it is weak or absent the conditions of deposit were more rapid, without the intervals and changes necessary for the production of the distinctly stratified structure.

False-bedding, Current-bedding.—Some strata, particularly sandstones, are marked by an irregular lamination, wherein the laminae, though for short distances parallel to each other, are oblique to the general stratification of the mass, at constantly varying angles and in different directions. The accompanying section (fig. 9) illustrates this

FIG. 9.—Section of false-bedded strata on the coast of Waterford.¹

structure, which is known by the name of false-bedding or current-bedding. The finer lines in this drawing represent the laminae of deposit, the stronger lines mark successive surfaces on which these laminae were laid down. Such a structure points to frequent changes in the direction of the currents by which the sediment was carried along and deposited. Sand pushed over the bottom of a sheet of water by varying currents tends to accumulate irregularly in bands and ridges, which often advance with a steep slope in front. The upper and lower surfaces of the bank or bed of sand may remain parallel with each other as well as with the underlying bottom, yet the successive laminae composing it may lie at an angle of 30° or even more. We may illustrate this structure by the familiar formation of a railway embankment. The top of the embankment on which the permanent way is to be laid is kept level, but the advancing end of the earth-work shows a steep slope over which the

¹ The woodcuts in this Part are (with the exception of Nos. 20 and 31) from the article GEOLOGY in the last edition of the *Encyc. Brit.*, written by the late J. B. Jukes, F.R.S.

workmen are constantly discharging waggon-loads of rubbish. Hence the embankment, if cut open longitudinally, would present a "false-bedded" structure, for it would be found to consist of many irregular layers inclined at a high angle in the direction in which the formation of the mound had advanced. In the accompanying figure (fig. 10) the water

FIG. 10.—Section illustrating the production of false-bedding.

moving in the direction of the arrow may drop sand at *b*, which will correspond in lamination with the general stratification of the locality; but when the current reaches the steep front of one of the advancing sand sheets it will allow the sand to roll down the slope, and may continue to bring fresh supplies of sediment until the slope is gradually effaced. Now and then, however, instead of laying down sediment, a current of greater strength than usual may appear and sweep away portions of the sediment already deposited.

Irregularities of Bedding due to Inequalities of Deposition or of Erosion.—A sharp ridge of sand or gravel may be laid down under water by current-action of some strength. Should the motion of the water diminish, finer sediment may be brought to the place and be deposited around and above the ridge. In such a case the stratification of the later accumulation will end off abruptly against the flanks of the older ridge, which will appear to rise up through the overlying bed. In fig. 11, for example, the lower bed

FIG. 11.—Mound of clay with ironstone balls (*a*), covered by beds of coal (*bb*).

seems to have been locally heaped up into the shape of a mound or ridge before the coal was accumulated over it. Appearances of this kind are not uncommon in some coal-fields, where they are known to the miners as "rolls," "swells," or "horses' backs." A structure exactly the reverse of the preceding occurs where a stratum has been scooped out before the deposition of the layers which cover it. This has often been observed in mining for coal. Channels have been cut out of a coal-seam, or rather out of the bed of vegetation which ultimately became coal, and these channels, ramifying and winding sometimes like those of streamlets on flat ground, have been filled up with sandy

FIG. 12.—Section of New Red Sandstone, road-cutting near Wolverhampton. 1, Red and white clay or marl; 2, Brown sandstone with irregular patches of marl; 3, Red marl, partially eroded before the deposition of 4, Brown sandstone eroded before the formation of 5, Calcareous sandstone or coralline.

or muddy sediment. In fig. 12 a section is given of a remarkable series of such erosions, where beds of clay and sandstone have been extensively denuded in the intervals

between the deposit of the successive beds. In these and similar cases it is evident that the erosion took place contemporaneously with the accumulation of the deposits as a whole. We cannot tell, of course, how long an interval elapsed between the formation of a given stratum and that of the next stratum which lies upon its eroded surface, nor how much depth of rock may have been removed in the erosion. When, however, as in the instances with which we are dealing, the structure occurs among conformable strata, evidently united as one lithologically continuous series of deposits, we may reasonably infer that the missing portions are of small moment and that the erosion was merely due to the irregular and more violent action of the very currents by which the sediment of the successive strata was supplied.

The case is very different when the eroded strata are inclined at a different angle to those above them, and are strongly marked off by lithological distinctions. In some of the coal-mines in central Scotland, for instance, deep channels have been met with entirely filled with sand, gravel, or clay belonging to the general superficial drift of the country. These channels have evidently been water-courses worn out of the coal-measure strata at a comparatively recent geological period, and subsequently buried under the glacial accumulations. There is a complete discordance between them and the Palæozoic strata below, pointing to the existence of a vast interval of time.

Ripple-mark.—The surface of many beds of sandstone is marked with lines of wavy ridge and hollow, such as may be seen on any shore from which the tide has retired. This kind of surface is known as "ripple-mark." It may be formed on dry blown sand by the action merely of the wind, and it is of everyday occurrence under shallow water, not merely on sea-shores, but on the floors of lakes and of river-pools. The water, gently agitated by the wind in a given direction, throws the surface of the underlying sediment into ripples which tend to run at right angles to the course of movement. But as the wind veers from point to point, producing corresponding changes in the direction of the water-currents, the ripples on the bottom are not strictly parallel, but often coalesce, intersect, and undulate in their course. Their general direction, however, suffices to indicate the quarter whence the chief movement of the water has come. No satisfactory inference can be drawn from the existence of a rippled surface as to the depth of water in which the sediment was accumulated. As a rule it is in water of only a few feet or yards in depth that ripple-mark is formed. But it may be produced at any depth to which the agitation caused by wind on the upper waters may extend.

On an ordinary beach each tide usually effaces the ripple-marks made by its predecessor, and leaves a new series to be obliterated by the next tide. But where the markings are formed in water which is always receiving fresh accumulations of sediment, a rippled surface may be gently over-spread by the descent of a layer of sediment upon it and may thus be preserved. Another series of ripples may then be made in the overlying layers, which in turn may be buried and preserved under a renewed deposit of sand. In this way a considerable thickness of such ripple-marked strata may be accumulated, as has frequently taken place among geological formations of all ages.

An examination of any sandy beach from which the sea has recently retired brings before us many modifications of the perfect ripple-mark. The ridges may be seen to grow more and more notched and irregular, until at last the beach seems to be dotted over with little, flat, dome-shaped mounds, or as if the ridges of the ripple-mark had been furrowed across. These modifications are doubtless due to the partial effacement of the ridges by subsequent action

of the water agitated by wind from a different quarter. Such indications of shallow-water conditions may often be observed among old arenaceous deposits, as in the Cambrian and Silurian rocks. In like manner we may frequently detect, among these ancient formations, small isolated or connected linear ridges directed from some common quarter, like the current-marks frequently to be found behind projecting fragments of shell, stones, or bits of sea-weed on a beach from which the tide has just retired.

Sun-cracks, Rain-pittings, &c.—Proofs may not infrequently be found that during deposition aqueous strata have been laid bare to air and sun. The nature and validity of this evidence will be best ascertained by observations made at the margin of the sea, or of any inland sheet of water, which from time to time leaves tracts of mud or fine sand exposed to sun and rain. The way in which the muddy bottom of a dried-up pool cracks into polygonal cakes when exposed to the sun may be illustrated abundantly among geological formations of all ages. These desiccation-cracks, or sun-cracks, could not have been produced so long as the sediment lay under water. Their existence therefore among any strata proves that the surface of rock on which they lie was exposed to the air and dried before the next layer of water-borne sediment was deposited upon it.

With these markings are not infrequently associated prints of rain-drops. The familiar effects of a heavy shower upon a surface of moist sand or mud may be witnessed among rocks even as old as parts of the Cambrian system. In some cases the rain-prints are found to be ridged up on one and the same side in such a manner as to indicate that the rain-drops as they fell were driven along in a slanting direction. The prominent side of the markings therefore indicates the side towards which the wind blew.

Numerous proofs of shallow shore-water, and likewise of exposure to the air, are supplied by markings left by animals. Castings and trails of worms, tracks of mollusks and crustaceans, fin-marks of fishes, footprints of birds, reptiles, and mammals, may all be preserved and give their evidence regarding the physical conditions under which sedimentary formations were accumulated. It may frequently be noticed that such impressions are associated with ripple-marks, rain-prints, or sun-cracks; so that more than one kind of evidence may be gleaned from a locality to show that it was sometimes laid bare of water.

Gas-spurts.—The surfaces of some strata, usually of a dark colour and containing much organic matter, may be observed to be raised into little heaps of various indefinite shapes, not, like the heaps associated with worm burrows, connected with pipes descending into the rock, nor composed of different material from the surrounding sandstone or shale. These may be conjectured to be due to the intermittent escape of gas from the decomposing organic matter in the original sand or mud, as we may sometimes witness in operation among the mud flats of rivers and estuaries. On a small scale these protrusions of the upper surface of a deposit may be compared with the well-known mud-lumps at the mouths of the Mississippi, where the muddy bottom rises into mounds sometimes to a height of several yards above the water, from the top of which great quantities of carburetted hydrogen gas make their escape, together with water and mud.

Concretions.—Many sedimentary rocks are marked by the occurrence of concretions in them, either distinct in aspect and composition from the general mass of the rock, or forming really part of that mass, though separated from the rest by their being agglutinated into concretionary forms. Such concretions, where they differ in petrographical characters from the surrounding matter, are almost invariably of original or contemporaneous formation, that is, were formed at the same time as the strata among which they

lie. Where, however, they appear to be merely compacted portions of the stratum, they may be regarded as generally due to some subsequent change effected upon the rock.

Contemporaneous concretions most commonly consist of carbonate of iron, carbonate of lime, or silica. Many clay-ironstone beds assume a nodular form, and this mineral occurs abundantly in the shape of separate nodules in shales and clay-rocks. The nodules have frequently formed round some organic body such as a fragment of plant, a shell, bone, or coprolite. That the carbonate of iron was slowly precipitated during the formation of the bed of shale in which its nodules lie may often be satisfactorily proved by the lines of deposit passing continuously through the nodules. In many cases the internal first-formed parts of a nodule have contracted more than the outer and more compact crust; and have cracked into open polygonal spaces which are commonly filled with calcite. Similar concretions of carbonate of lime occur in some clays and in connexion with limestones. Concretions of silica occur in limestone of many geological ages (see *ante*, p. 239). The flints of the English chalk are a familiar example, but similar siliceous concretions occur even in Lower Silurian limestones. The

FIG. 13.—Sketch of limestone-beds, with concretions of white chert, Middleton Moor, Derbyshire.

silica in these cases has not infrequently been deposited round organic bodies such as sponges, sea-urchins, and mollusca, which are completely enveloped in it and have even themselves been silicified. Iron-bisulphide (pyrite or marcasite) often assumes the form of concretions, more

FIG. 14.—Sketch of part of a block of black chert in the limestone near Dublin.

particularly among clay-rocks, and these, though presenting many eccentricities of shape, round like pistol-shot or cannon-balls, kidney-shaped, botryoidal, &c., agree in usually possessing an internal fibrous radiated structure. Phosphate of lime is found as concretions in formations where the coprolites and bones of reptiles and other animals have been collected together.

Concretions produced subsequently to the formation of the rock may be observed in some sandstones, which, when exposed to the weather, decompose into large round balls. Some shales exhibit this structure in a still more striking manner, inasmuch as the concretions consist of the general mass of the laminated shale, and the lines of stratification pass through them and mark them out distinctly as superinduced upon the rock. Some magnesian limestones also

so concretionary as to resemble masses of conglomerate, yet the concretions, among all their fantastic shapes and with their acquired crystalline texture, may often be found to retain traces of the original stratification of the rock. Beds of rock-salt may likewise be observed to be marked with traces of a concretionary arrangement.

Order of Superposition—the Foundation of Geological Chronology.—As sedimentary strata are laid down upon one another in a more or less nearly horizontal position, the underlying beds must be older than those which cover them. This simple and obvious truth is termed the law of superposition. It furnishes the means of determining the chronology of rocks, and though other methods of ascertaining this point are employed, they must all be based originally upon the observed order of superposition. The only case where the apparent superposition may be deceptive is where the strata have been inverted. In the Alps, for example, the rocks composing huge mountain masses have been so completely overturned that the highest beds appear as if regularly covered by others which ought properly to underlie them. But these are exceptional occurrences, where the true order can usually be made out from other sources of evidence.

Alternations of Strata.—Though great variations occur in the nature of the strata composing a mass of sedimentary rocks, it may often be observed that certain repetitions occur. Sandstones, for example, are found to be interleaved with shale above, and then to pass into shale; the latter may in turn become sandy at the top and be finally covered by sandstone, or may assume a calcareous character and pass up into limestone. Such alternations bring before us the conditions under which the sedimentation took place. A sandstone group indicates water of comparatively little depth, moved by changing currents, bringing the sand now from one side now from another. The passage of such a group into one of shale points to a diminution in the motion and transporting power of the water, perhaps to a sinking of the tract, whereby only fine mud was then intermittently brought into it. The advent of a limestone above the shale serves to show that the water cleared, owing to a deflexion of the sediment-carrying currents, or to continued and perhaps more rapid subsidence, and that *Foramifera*, corals, crinoids, *Mollusca*, or other lime-secreting organisms, established themselves upon the spot. Shale overlying the limestone would tell of fresh inroads of mud, which destroyed the animal life that had been flourishing on the bottom; while a return of sandstone beds would mark how, in the course of time, the original conditions of troubled currents and shifting sandbanks returned. Such alternating groups of sandy, calcareous, and argillaceous strata are well illustrated among the Jurassic formations of England.

Associations of Strata.—Certain kinds of strata very commonly occur together, because the conditions under which they were formed were apt to arise in succession. One of the most familiar examples is the association of coal and fire-clay. A seam of coal is almost invariably found to lie on a bed of fire-clay, or on some argillaceous stratum. The reason of this union becomes at once apparent when we learn that the fire-clay formed the soil on which the plants grew that went to form the coal. Where the clay was laid down under suitable circumstances vegetation sprang up upon it. Again conglomerate and sandstone occur together rather than conglomerate and shale, because the agitation of the water which could form and deposit coarse detritus, like that composing conglomerate, was too great to admit of the accumulation of fine silt. For a similar reason we may look for shale or clay rather than sandstone as an accompaniment of limestone.

Relative Persistence of Strata.—Observation of what takes place on any lake bottom, estuary, or sea-margin

teaches that some kinds of sediment are much more widely spread than others, and prepares us to find that the same has been the case in past time, and therefore that some kinds of sedimentary rocks possess far greater persistence than others. As a general rule it may be said that the coarser the grain the more local the extent of a rock. Conglomerates are thus by much the most variable and inconstant of all sedimentary formations. They suddenly sink down from a thickness of several hundred feet to a few yards, or die out altogether, to reappear perhaps further on, in the same wedge-like or lenticular fashion. Sandstones are less liable to such extremes of inconstancy, but they too are apt to thin away and to swell out again. Shales are much more persistent, the same zone being often traceable for many miles. Limestones sometimes occur in thick local masses, as among the Silurian formations of Wales and Scotland, but they often also display remarkable continuity. Three thin limestone bands, each of them only 2 or 3 feet in thickness, and separated by a considerable thickness of intervening sandstones and shales, can be traced through the coal-fields of central Scotland over an area of at least 1000 square miles. Coal-seams also possess great persistence. The same seams, varying slightly in thickness and quality, may often be traced throughout the whole of an extensive coal-field.

What is thus true of individual strata may be affirmed also of groups of such strata. A thick mass of sandstone will be found as a rule to be more continuous than one of conglomerate, but less so than one of shale. A series of limestone-beds will usually be found to stretch further than either of them. But even to the most extensive stratum or group of strata there must be a limit. It must end off and give place to others, either suddenly, as a bank of shingle is succeeded by the sheet of sand heaped against its base, or very gradually, by insensibly passing into other strata on all sides.

Great variations in the character of stratified rocks may frequently be observed in passing from one part of a country to another along the outcrop of the same rocks. Thus at one end we may meet with a thick series of sandstones and shales which, traced in a certain direction, may be found passing into limestones. A group of strata may consist of massive conglomerates at one locality, and may graduate into fine fissile flagstones in another. A thick mass of clay may be found to alternate more and more with shelly sands as it is traced outward, until it loses its argillaceous nature altogether. No difficulty need be felt in admitting the strict contemporaneity of these diverse layers of sediment. At the present time we see how coarse shingle may be formed along the beach at the same time that the finest mud is being laid down on the same sea-bottom further from land. Could we raise up that bottom, we should doubtless find as gradual a passage from the littoral to the deeper water deposits as we do among the geological formations of the earth's crust. The existing differences of character between the deposits of the shore and of the open sea would no doubt continue to be maintained, with slight geographical displacements, even if the whole area were undergoing subsidence, giving rise to a thick group of littoral beds in one tract and of deeper-water accumulations at another. In like manner among the formations of former geological periods the same conditions of deposit appear sometimes to have continued for a considerable period. Hence the thick Mountain or Carboniferous Limestone of Derbyshire is gradually replaced northwards by the thick sandstones, shales, ironstones, and coal seams of Scotland.

Overlap.—When strata have been laid down in a subsiding region wherein the area of deposit gradually increased, the sediment must have spread over a progressively augmenting surface. By this means the later portions of a sedimentary series will extend beyond the limits of the older

parts, and will repose directly upon the shelving bottom, with none of those older strata underneath them. This relation is called *Overlap* (see fig. 59). The higher or newer members are said to overlap the older. This structure may often be detected among formations of all geological ages. It brings before us the shore line of ancient land-surfaces, and shows how, as these sank under water, the gravels, sands, and silts gradually advanced and covered them.

Relative Lapse of Time represented by Strata and by the Intervals between them.—Of the absolute length of time represented by any strata or groups of strata we can form no satisfactory estimates. Certain general conclusions may indeed be drawn, and comparisons may be made between different series of rocks. Sandstones full of false-bedding were probably accumulated more rapidly than finely-laminated shales or clays. It is not uncommon in certain Carboniferous formations to find huge coniferous trunks imbedded in an inclined position in sandstone. These trees seem to have been carried along and to have sunk, their heavier or root-end touching the bottom, and their upper end pointing upward in the direction of the current, exactly as in the case of the snags of the Mississippi. The continuous deposit of sand at last rose above the level of the trunks and buried them. It is clear then that the rate of deposit must have been sufficiently rapid to have allowed a mass of 20 or 30 feet of sand to accumulate before the decay of the wood; though modern instances are known where, under certain circumstances, submerged trees may last for some centuries. Continuous layers of the same kind of deposit suggest a persistence of geological conditions; numerous alternations of different kinds of sedimentary matter point to vicissitudes or alternations of conditions. As a rule, we should infer that the time represented by a given thickness of similar strata was less than that shown by the same thickness of dissimilar strata, because the changes needed to bring new varieties of sediment into the area of deposit would usually require the lapse of some time for their completion. But this conclusion might often be erroneous. It would be best supported when, from the very nature of the rocks, wide variations in the character of the water-bottom could be established. Thus a group of shales followed by a fossiliferous limestone would almost always mark the lapse of a much longer period than an equal depth of sandy strata. Limestones made up of organic remains which lived and died upon the spot, and whose remains are crowded together generation above generation, must have demanded many years for their formation.

But in all speculations of this kind we must bear in mind that the length of time represented by a given depth of strata is not to be estimated merely from their thickness or lithological characters. It has already been pointed out that the interval between the deposit of two successive laminae of shale may have been as long as, or even longer than, that required for the formation of one of the laminae. In like manner, the interval needed for the transition from one stratum or kind of strata to another may often have been more than equal to the time required for the formation of the strata on either side. But the relative chronological importance of the bars or lines in the geological record can seldom be satisfactorily discussed merely on lithological grounds. This must mainly be decided on the evidence of organic remains, as will be shown in part v. By this kind of evidence it can be made nearly certain that the intervals represented by strata were in many cases much shorter than those not so represented,—in other words, that the time during which no deposit of sediment went on was longer than that wherein deposit did take place.

Groups of Strata.—Passing from individual strata to large masses of stratified rock, the geologist finds it needful

for convenience of reference to subdivide these into groups. He avails himself of two bases of classification—(1) lithological characters, and (2) organic remains.

1 The subdivision of stratified rocks into groups according to their mineral aspect is an obvious and easily applied classification. Moreover, it often serves to connect together rocks formed continuously in certain circumstances which differed from those under which the strata above and below were laid down,—so that it expresses natural and original subdivisions of strata. In the middle of the English Carboniferous system of rocks, for example, a zone of sandy and pebbly beds occurs, known as the Millstone Grit. No abrupt and sharp line can be drawn between these strata and those above and below them. They shade upward and downward into the beds between which they lie. Yet they form a conspicuous belt, traceable for many miles by the scenery to which it gives rise. The red rocks of central England, with their red sandstones, marls, rock-salt, and gypsum, form likewise a well-marked group or rather series of groups. It is obvious, however, that characters of this kind, though sometimes wonderfully persistent over wide tracts of country, must be at best but local. The physical conditions of deposit must always have been limited in extent. A group of strata showing great thickness in one region will be found to die away as it is traced into another. Or its place is gradually taken by another group which, even if geologically contemporaneous, possesses totally different lithological characters. Just as at the present time a group of sandy deposits gradually gives place along the sea-floor to others of mud, and these to others of shells or of gravel, so in former geological periods contemporaneous deposits were not always lithologically similar. Hence mere resemblance in mineral aspect usually cannot be regarded as satisfactory evidence of contemporaneity except within comparatively contracted areas. The Carboniferous Limestone of Ireland is a thick calcareous group of rocks, full of corals, crinoids, and other organisms, which bear witness to the formation of these rocks in the open sea. But if these limestones, with their characteristic marine fossils, are traced into the north of England and Scotland, they are found to pass into sandstones and shales, with numerous coal-seams, and only a few thin beds of limestone. The soft clay beneath the city of London is represented in the Alps by hard schists and contorted limestones. We conclude therefore that lithological agreement when pushed too far is apt to mislead us, partly because contemporaneous strata often vary greatly in their lithological character, and partly because the same lithological characters may appear again and again in different ages. By trusting too implicitly to this kind of evidence, we may be led to class together rocks belonging to very different geological periods, and on the other hand to separate groups which really, in spite of their seeming distinction, were formed contemporaneously.

2. It is by the remains of plants and animals imbedded among the stratified rocks that the most satisfactory subdivisions of the geological record can be made, as will be more fully stated in parts v. and vi. A chronological succession of organic forms can be made out among the rocks of the earth's crust. A certain common facies or type of fossils is found to characterize particular groups of rock, and to hold true even though the lithological constitution of the strata should greatly vary. Moreover, though comparatively few species are universally diffused, they possess remarkable persistence over wide areas, and even when they are replaced by others, the same general facies of fossils remains. Hence the stratified formations of two countries geographically distant, and having little or no lithological resemblance to each other, may be compared and paralleled zone by zone, simply by means of their enclosed organic remains.

II. JOINTS.

All rocks are traversed more or less distinctly by vertical or highly inclined divisional planes termed *Joints*. Soft rocks indeed, such as loose sand and uncompacted clay, do not show these lines; but wherever a mass of clay has been subjected to some pressure and consolidation, it will usually be found to have acquired them. It is by means of the intersection of joints that rocks can be removed in blocks; the art of quarrying consists in taking advantage of these natural planes of division. Joints differ in character according to the nature of the material which they traverse; those in sedimentary rocks are usually distinct from those in crystalline masses.

1. *In Sedimentary Rocks.*—Joints vary in sharpness of definition, in the regularity of their perpendicular and horizontal course, in their lateral persistence, in number, and in the directions of intersection. As a rule, they are most sharply defined in proportion to the fineness of grain of the rock. In limestones and close-grained shales, for example, they often occur so clean-cut as to be invisible until revealed by fracture or by the slow disintegrating effects of the weather. The rock splits up along these concealed lines of division whether the agent of demolition be the hammer or frost. In coarse-textured rocks, on the other hand, joints are apt to show themselves as irregular rents along which the rock has been shattered, so that they present an uneven sinuous course, branching off in different directions. In many rocks they descend vertically in straight lines at not very unequal distances, so that the spaces between them are thus marked off into so many wall-like masses. But this symmetry often gives place to a more or less tortuous course with lateral joints in various random directions, more especially where the different strata vary considerably in lithological characters. A single joint may be traced sometimes for many yards, or even for several miles, more particularly when the rock is fine-grained, as in limestone. But where the texture is coarse and unequal, the joints, though abundant, run into each other in such a way that no one in particular can be identified for so great a distance. The number of joints in a mass of stratified rock varies within wide limits. Among strata which have undergone little disturbance the joints may be separated from each other by intervals of several yards. But in other cases where the terrestrial movement appears to have been considerable, the rocks are so jointed as to have acquired therefrom a fissile character that has nearly or wholly obliterated their tendency to split along the lines of bedding.

An important feature in the joints of stratified rocks is the direction in which they intersect each other. As the result of observation we learn that they possess two dominant trends, one coincident in a general way with the direction in which the strata are inclined to the horizon, and the other running transversely at a right angle or nearly so. The former set is known as *dip-joints*, because they run with the *dip* or inclination of the rocks, the latter is termed *strike-joints*, inasmuch as they conform to the general *strike* or mean outcrop. It is owing to the existence of this double series of joints that ordinary quarrying operations can be carried on. Large quadrangular blocks can be wedged off, which would be shattered if exposed to the risk of blasting. A quarry is usually worked to the *dip* of a rock, hence the strike-joints form clean-cut faces in front of the workmen as they advance. These are known as "backs," and the dip-joints which traverse them as "cutters." The way in which this double set of joints occurs in a quarry may be seen in fig. 15, where the parallel lines which traverse the shaded and unshaded faces mark the successive strata. The broad white spaces running along the length

of the quarry behind the seated figure are strike-joints or "backs," traversed by some highly inclined lines which mark the position of dip-joints or "cutters." The shaded

FIG. 15.—Joints in limestone quarry near Mallow, co. Cork. (G. V. Du Noyer.)

ends looking towards the spectator are "cutters" from which the rock has been quarried away on one side.

In some conglomerates the joints may be seen traversing the enclosed pebbles as well as the surrounding matrix. Large blocks of hard quartz are cut through by them as sharply as if they had been sliced in a lapidary's machine, and the same joints can be traced continuously through many yards of the rock. Such facts show that the agency to which the jointing of rocks was due must have operated with considerable force.¹ Further indication of movement is often supplied by the rubbed and striated surfaces of joints. These surfaces, termed *slickensides*, have evidently been ground against each other. They are often coated with hæmatite, calcite, chlorite, or other mineral, which has taken a cast of the striae and then seems itself to be striated.

Joints form natural lines for the passage downward and upward of subterranean water. They likewise furnish an effective lodgment for surface water which, frozen by a lowering of temperature, expands into ice, and wedges off blocks of rock in the manner already described. As they serve, in conjunction with bedding, to divide stratified rocks into large quadrangular blocks, their effect on cliffs and other exposed masses of rock is seen in the apparently splintered, dislocated aspect so familiar in mountain scenery.

Occasionally a prismatic or columnar form of joints may be observed among stratified rocks. When this occurs among unaltered strata it is usually among those which have been chemically formed, as in gypsum, where, as observed by Mr Jukes in the Paris Basin, some beds are divided from top to bottom by vertical hexagonal prisms. A columnar structure has often been superinduced upon stratified rocks by contact with intrusive igneous masses. Sandstones, shale, and coal may be observed in this condition. The columns diverge perpendicularly to the surface of the injected and altering substance, so that when the latter is vertical the columns are horizontal, or when it undulates the columns follow its curvatures. Beautiful examples of this character occur among the coal-seams of Ayrshire.

2. *In Crystalline (Igneous) Rocks.*—While in stratified rocks the divisional planes consist of lines of bedding and of joint, cutting each other usually at a high if not a right angle, in massive igneous rocks they include joints only; and as these do not as a rule present the same parallelism as lines of bedding, unstratified rocks, even though as full of joints, have not the same regularity of arrangement as in the stratified formations. Granite, for example, is traversed by two sets of chief or "master-joints," cutting each other somewhat obliquely. Their effect is to divide the rock into long quadrangular, rhomboidal, or even polygonal columns.

¹ See an interesting series of experiments by M. Daurière (*Comptes Rendus*, lxxvi., 1878) on the production of faults and joints.

But a third set may usually be noticed cutting across the columns, though less continuous and dominant than the others. When these transverse joints are few in number or occasionally absent, columns many feet in length can be quarried out entire. Such monoliths have been from early times employed in the construction of obelisks and pillars.

In rocks of finer grain than granite, such as many diorites and dolerites, the numerous perpendicular joints give the rock a prismatic character. The prisms however are unequal in dimensions, as well as in the number and proportions of their sides, a frequent diameter being 2 or 3 feet, though they may sometimes be observed three times thicker, and extending up the face of a cliff for 300 or 400 feet. It is by means of joints that precipitous faces of rocks are produced and retained, for, as in the case of those in stratified masses, they serve as openings into which

FIG. 16.—Joints in granite, Killiney Hill, Dublin. (G. V. Du Noyer.)

frust drives every year its wedges of ice, whereby huge slices are stripped off. They likewise give rise to the formation of those fantastic pinnacles and fretted buttresses so generally to be observed among igneous rocks in which they occur.

But undoubtedly the most striking series of joints to be found among igneous rocks is in the regularly columnar, or as it is often called, basaltic structure. This structure has been already (*ante*, p. 249) described in connexion with modern volcanic rocks. It may be met with in rocks of all ages. It is as well displayed among the felsites of the Lower Old Red Sandstone, and the basalts of the Carboniferous Limestone in central Scotland, as among the Tertiary lavas of Auvergne or the Vivarais.

3. In *Foliated Rocks*.—The schists likewise possess their joints, which approximate in character to those among the massive igneous rocks, but they are on the whole less distinct and continuous, while their effect in dividing the rocks into oblong masses is considerably modified by the transverse lines of foliation. These lines play somewhat the same part as those of stratification do among the stratified rocks, though with less definiteness and precision.

III. INCLINATION OF ROCKS.

The most casual observation is sufficient to satisfy us that the rocks now visible at the earth's surface are seldom in their original position. We meet with sandstones and conglomerates composed of water-worn particles, yet forming the angular scarps of lofty mountains; shales and clays full of the remains of fresh-water shells and land-plants, yet covered by limestones made up of marine organisms, and these limestones rising into great ranges of hills, or undulating into fertile valleys, and passing under the streets of busy towns. Such facts, now familiar to every reader, and even to many observers who know little or nothing of systematic geology, point unmistakably to the conclusion that the rocks have in many cases been formed under water, sometimes in lakes, more frequently in the sea, and that they have been elevated into land.

But further examination discloses other and not less

convincing evidence of movement. Judging from what takes place at the present time on the bottoms of lakes and of the sea, we confidently infer that when the strata now constituting so much of the solid framework of the land were formed, they were laid down either horizontally or at least at low angles. When, therefore, we find them inclined at all angles, and even standing on end, we conclude that they have been disturbed. Over wide spaces they have been upraised bodily with little alteration of their original horizontality; but in most places some departure from that original position has been effected.

The inclination thus given to rocks is termed their dip. Its amount is expressed in degrees measured from the plane of the horizon. Thus a set of rocks half-way between the horizontal and vertical position would be said to dip at an angle of 45°, while if vertical they would be marked with the angle of 90°. The edges of strata, where they come up to the surface, are termed their *outcrop* or *baset*. When they *crop out*, that is, rise to the surface, along a perfectly level piece of ground, the outcrop runs at a right angle to the dip. But any inequalities of the surface, such as valleys, ravines, hills, and ridges will cause the outcrop to describe a circuitous course, even though the dip should remain perfectly steady all the while. If a line of precipitous gorge should run directly with the dip, the outcrop will there be coincident with the dip. The occurrence of a

FIG. 17.—Vertical strata, originally deposited horizontally or at low angles.

gently shelving valley in that position will cause the outcrop to descend on one side and to mount in a corresponding way on the other, so as to form a V-shaped indentation in its course. A ridge, on the other hand, will produce a deflexion in the opposite direction. Hence a series of parallel ridges and valleys running in the same direction as the dip of the strata underneath would cause the outcrop to describe a widely serpentinous course. Again, should the rocks be vertical, the outcrop will necessarily correspond with the dip, and continue to do so irrespective altogether of any irregularities of the ground. The lower therefore the angle of inclination the greater is the effect of surface inequalities upon the line of outcrop; the higher the angle the less is that influence, till when the beds stand on end it ceases.

A line drawn at a right angle to the dip is called the *strike* of the rocks. From what has just been said this line must coincide with outcrop when the surface of the ground is quite level, and also when the beds are vertical. At all other times they are not strictly coincident, but the outcrop wanders to and fro across the strike according to the changes in the angle of inclination and in the form of the ground. The strike may be a straight line or may curve rapidly in every direction, according to the behaviour of the dip. If, for instance, a set of beds dips for half a mile continuously to the north, the strike will run for that distance as a straight east and west line. If the dip gradually changes to north-west and west, and then by south-west to south, it is obvious that the strike must curve round by north-east, north, and north-west till it once more

becomes parallel with its former course. Both of the parallel lines of strike run in an east-and-west direction, but in the one the dip is to the south, and in the other to the north.

The strike may be conceived as always a level line on the plane of the horizon, so that no matter how much the ground may undulate, or the outcrop may vary, or the dip may change, the strike will remain level. Hence in mining operations it is commonly spoken of as the *level-*

course or *level-bearing*. A level or underground road-way, driven through a coal-seam at right angles to the dip, will undulate in its course if the dip changes in direction, but it may be made perfectly level and kept so throughout a whole coal-field so long as it is not interfered with by any dislocations or other disturbances of the regularity of the rocks.

The accompanying figures (figs. 18 and 19) will serve to show some of these terms as expressed on maps and

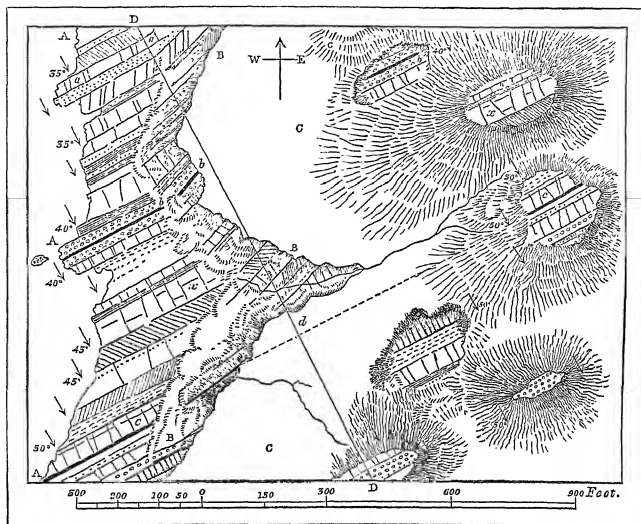

FIG. 18.—Geological map of a portion of a rocky coast-line, and the country inland. (J. B. Jukes.)

sections. Fig. 18 represents a geological map in which a series of strata dips in a south-south-easterly direction (S. 28° E.). The angle of inclination increases from 35° at the northern to 50° at the southern end of the beach. On the flat shore (AA) outcrop and strike coincide, but along the inner margin, where the ground ascends in a line or

cliff (BB) to the inland country (CC), the outcrop is seen to be deflected a little so as to cross the plateau along a slightly more northerly line than on the beach. A section drawn at a right angle to the strike along the line DD would show the structure represented in fig. 19. Such a section, expressing graphically the result of careful measure-

FIG. 19.—Section along the line DD on fig. 18.

ment in the field, would give not only the order of succession of beds at the surface, but their actual depth at any point beneath it. Thus a bore or shaft sunk at the point marked *d* on the map would have to pass through rather more than 425 feet of rock before reaching the stratum *b*.

The total thickness of rock measured at right angles to the dip in fig. 19 is somewhat more than 850 feet. These various strata, if restored to their original position, would lie one over the other to that depth. If they were on end they would occupy exactly that breadth of ground. But

the inclined position of strata makes them cover more horizontal space; in the present instance it increases that space to 1200 feet.

A convenient rule was given many years ago by the late Mr Charles Maclaren of Edinburgh for estimating the thickness of strata inclined at angles of less than 45° . The real thickness of a mass of inclined strata is $\frac{1}{2}$ th of its apparent thickness for every 5° of dip. Thus if a set of beds dip steadily in one direction at 5° for a horizontal space of 1200 feet measured across the strike, their actual thickness will be $\frac{1}{2}$ th or 100 feet. If the dip be 15° the true thickness will be $\frac{1}{3}$ ths or 400 feet, and so on.

IV. CURVATURES OF ROCKS.

A little reflexion will show that though, so far as regards the trifling portions of the rocks visible at the surface, we might regard the inclined surfaces of the strata as parts of straight lines, they must nevertheless be parts of large curves. Take, for example, the section given in fig. 19. At the north end of that section we observe the beds to plunge one after another into the earth at an angle of 35° . By degrees the inclination increases until it reaches 50° . As there is no dislocation or abrupt change of angle, but a gradual transition, it is evident that the beds at the north end cannot proceed indefinitely downward at the same angle which they have at the surface, but must bend round to accommodate themselves to the higher inclination which sets in southwards. By prolonging the lines of the beds for some way beneath the sea-level, we can show graphically the nature of the curve. In every instance therefore where, in walking over the surface, we traverse a series of strata which gradually, and without dislocations, increase or diminish in inclination, we cross part of a great curvature in the strata of the earth's crust.

Such foldings, however, can often be distinctly seen, either on some cliff or coast-line, or in the traverse of a piece of hilly or mountainous ground. The observer cannot long continue his researches in the field without discovering that the rocks of the earth's crust have been almost everywhere thrown into curves, usually so broad and gentle as to escape observation except when specially looked for. The outcrop of beds at the surface is commonly the truncation of these curves. The strata must once have risen above the present surface, and in many cases may be found descending to the surface again with a contrary dip, the intervening portion of the undulation having been worn away.

If then the inclination of rocks is so closely connected with their curvature, a corresponding relation must hold between their strike and curvature. In fact, the prevalent strike of a region is determined by the direction of the axes of the great folds into which the rocks have been thrown. If the curves are gentle and inconstant there will be a corresponding variation in the strike. But should the rocks be strongly plicated, there will necessarily be the most thorough coincidence between the strike and the direction of the plication.

The curvature occasionally shows itself among horizontal or gently inclined strata in the form of an abrupt inclination, and then an immediate resumption of the previous flat or sloping character. The strata are thus bent up and continue on the other side of the tilt at a higher level. Such bends are called *monoclines* or *monoclinical folds*, because they present only one fold, or one half of a fold, instead of the two which we see in an arch or trough. The most notable instance of this structure in Britain is that of the Isle of Wight, of which a section is given in fig. 20. The Cretaceous rocks on the south side of the island rapidly rise in inclination till they become nearly vertical.

The Lower Tertiary strata follow with a similar steep dip, but rapidly flatten down towards the north coast. Some

FIG. 20.—Section of the Isle of Wight—a monoclinical curve. *a*, Chalk; *b*, Woolwich and Reading beds; *c*, London clay; *d*, Dagsht series; *e*, Headon series; *f*, Osborne and Bembridge series.

remarkable cases of the same structure have been brought to light by Mr J. W. Powell in his survey of the Colorado region.

It much more frequently happens that the strata have been bent into arches and troughs, so that they can be seen dipping under the surface on one side of the axis of a fold, and rising up again on the other side. Where they dip away from the axis of movement the structure is termed an *anticline* or *anticlinal fold*; where they dip towards the

FIG. 21.—Plan of anticlinal and synclinal folds.

axis, it is a *syncline* or *synclinal fold*. The diagram in fig. 21 may be taken to represent a series of strata (1-17) thrown into an anticline (AA') and syncline (BB'). A section drawn across these folds in the line CD would show

FIG. 22.—Section of anticlinal and synclinal folds on the line CD (fig. 21).

the structure given in fig. 22. Here we see that, at the part of the anticlinal axis (A) where the section crosses, bed No. 4 forms the crown of the arch, Nos. 1, 2, and 3 being concealed beneath it. On the east side of the axis the strata follow each other in regular succession as far as No. 13, which, instead of passing here under the next in order, turns up with a contrary dip and forms the centre of a trough or syncline (B). From underneath No. 13 on the east side, the same beds rise to the surface which passed beneath it on the west side. The particular bed marked EF has been entirely removed by denudation from the top of the anticline, and is buried deep beneath the centre of the syncline.

Such foldings of strata must always die out unless they are abruptly terminated by dislocations. In the cases given in fig. 21, both the arch and trough are represented as diminishing, the former towards the north, the latter towards the south. The observer in passing northwards

along the axis of that anticline finds himself getting into progressively higher strata, as the fold sinks down. On the other hand, in advancing southwards along the synclinal axis, he loses stratum after stratum and gets into lower portions of the series. When a fold diminishes in this way it is said to "nose out." In fig. 21 there is obviously a general inclination of the beds towards the north, besides the outward dip from the anticline and the inward dip from the syncline. Hence the anticline noses out to the north and the syncline to the south.

It occasionally happens that the maximum movement either of upheaval or subsidence has taken place not along a line of axis but at some one point. Hence arise, on the one hand, dome-shaped elevations of strata where the dip is outward from a centre (quaquaversal), round which the beds are disposed in successive parallel layers or rings, and, on the other hand, circular basin-shaped depressions, towards the centre of which there is a general inclination of the rocks.

So great has been the compression to which rocks have been subjected during the process of curvature that the folds may often be found inverted. This has taken place

FIG. 23.—Section of inclined axes, showing consequent inversion of strata.

abundantly in regions of great plication. The Silurian uplands of the south of Scotland, for instance, have the arches and troughs tilted in one direction for miles together, so that in one half of each of them the strata lie bottom upwards. It is in large mountain-chains, however, that inversion can be seen on the grandest scale. The Alps furnish numerous striking illustrations. On the north side of that chain the older Tertiary rocks have been so completely turned over for many miles that the lowest beds now form the tops of the hills, while the highest lie deep below them. Individual mountains, such as the Glärnisch, present stupendous examples of inversion, great groups of strata being folded over and over above each other as we might fold carpets.

FIG. 24.—Curved and contorted rocks, near Old Head of Kinsale. (Du Noyer.)

Where curvature has been carried so far, we may nearly always discover localities at which it has been so intensified that the strata have been corrugated and crumpled till it becomes almost impossible to follow out any particular bed through the disturbance. On a small scale instances of such extreme contortion may now and then be found at landslides, where fissile shales have been pressed forward by advancing heavy masses of more solid rock. But it is of course among the more plicated parts of mountain-chains that the structure receives its best illustrations. Few travellers who have passed the upper end of the Lake of Lucerne can have failed to notice the remarkable cliffs of contorted rocks near Flüelen. But innumerable examples of equal or even

superior grandeur may be observed among the more precipitous valleys of the Swiss Alps. No more impressive testimony could be given to the potency of the force by which mountains were upheaved.

V. DISLOCATIONS OF ROCKS.

The movements which the crust of the earth has undergone have not only folded and corrugated the rocks, but have fractured them in all directions. These dislocations may be either simple *fissures*, that is, rents without any vertical displacement of the mass on either side, or *faults*, that is, rents where one side has been pushed up or has sunk down. It is not always possible in a shattered rock to discriminate between joints and true fissures. The joints indeed have sometimes served as lines along which fissuring has taken place. It is common to meet with traces of friction along the walls of fissures even when no proof of actual vertical displacement can be gleaned. The rock is more or less shattered on either side, and the contiguous faces present numerous slickensided surfaces. Mineral deposits may also commonly be observed encrusting the cheeks of a fissure, or filling up, together with broken fragments of rock, the space between the two walls.

In a large proportion of cases, however, there has been displacement as well as fracture, and the rents have become faults as well as fissures. Faults on a small scale are sometimes sharply-defined lines, as if the rocks had been

FIG. 25.—Section of clean-cut fault.

slid through and fitted together again after being shifted (fig. 25). In such cases, however, the harder portions of the dislocated rocks will usually be found slickensided. More frequently some disturbance has occurred on one or both sides of the fault. Sometimes in a series of strata the beds on the side which has been pushed up are bent down

FIG. 26.—Section of strata, bent at a line of fault.

against the fault, while those on the opposite side are bent up (fig. 26). Most commonly the rocks on both sides are considerably broken, jumbled, and crumpled, so that the line of fracture is marked by a belt or wall-like mass of fragmentary rock. Where a dislocation has occurred through materials of very unequal hardness, such as solid

limestone bands and soft shales, or where its course has been undulating, the relative shifting of the two sides has occasionally brought opposite prominences together so as to leave wider interspaces, as in fig. 27. The actual breadth

FIG. 27.—Section of fault, showing the alternate expansions and contractions due to the shifting of one side of a sinuous strata.

of a fault may vary from a mere chink into which the point of a knife could hardly be inserted up to a band of broken rock many yards wide. But in these latter cases we may usually suspect that so great a breadth of fractured materials has been produced not by a single fault but by a series of closely adjoining and parallel faults.

Faults are sometimes vertical, but are generally inclined. The largest faults, that is, those which have the greatest

FIG. 28.—Section of a vertical and inclined fault.

vertical displacement, slope at high angles, while those of only a few feet or yards may be inclined as low as 18° or 20° . The inclination of a fault from the vertical is called its *hade*. In fig. 28, for example, the fault between A and C being vertical has no hade, but that between C and B hades at an angle of 70° from the vertical to the right hand. The amount of displacement is represented as the same in both instances, so that the level of the bed *a* is raised between the two faults at C above the uniform horizon which it retains beyond them.

That faults are vertical displacements of parts of the earth's crust is most clearly shown when they traverse stratified rocks, for the regular lines of bedding and the originally flat position of these rocks afford a measure of the disturbance. Accordingly we may consider here the effects of faults as they traverse (1) horizontal, (2) inclined, or (3) undulating strata.

1. In the above section (fig. 28) two faults are supposed to traverse a set of horizontal strata, and to displace them in opposite directions. Hence the portion between them appears as if it had been pushed up, or as if the part on either side had slipped down. The amount of vertical displacement is measured from the end of any given stratum, say *a*, on one side of the fault, to its corresponding end on the other side. Suppose, for example, that the black band in fig. 29 represents a known stratum such as a seam of coal, which, having been explored in underground operations, is known to be cut by a fault at a depth of a hundred yards below the surface at A, and to lie 200 yards deep on the other side of the fault below B. The amount of displacement is the vertical distance between the two severed ends *a* and *b*. This is termed the *throw* of a fault. From these two sections (figs. 28 and 29) we see that the horizontal distance to which the two ends of a faulted stratum may be separated does not

depend upon the amount of throw but upon the angle of the hade. In the left-hand fault in fig. 28 there is no hade,

FIG. 29.—Measurement of the throw of a fault.

for the fault is vertical; consequently there is no lateral displacement. In fig. 29, however, where the fault hades considerably, there is a lateral shift of the bed, the end *a* being 150 yards to the left of *b*. In this example the lateral shift is half as much again as the vertical. It is obvious that a fault of this kind must seriously affect the value of a coal-field; for while the coal-seam might be worked up to *a* on the one side and to *b* on the other, there would be a space of 150 yards of barren ground between these two points where the seam never could be found. The lower the angle of hade the greater the breadth of such barren ground. Hence the more nearly vertical the lines of fault, the better for the coal-fields.

In the vast majority of cases faults hade in the direction of downthrow, in other words, they slope away from the side which has risen. Consequently the mere inspection of a fault in any natural or artificial section suffices in most cases to show which side has been elevated. In mining operations the knowledge of this rule is invaluable, for it decides whether a coal seam, dislocated by a fault, is to be sought for by going up or down. In fig. 29, for example, a miner working from the right and meeting with the fault at *b*, would know from its hading towards him that he must ascend to find the coal. On the other hand were he to work from the left and catch the fault at *a*, he would see that it would be necessary to descend. According to this rule a normal fault never brings one part of a bed below another part, so as to be capable of being pierced twice by the same vertical shaft. Exceptional cases, however, where the hade is reversed, do occasionally appear. In fig. 30 a series of strata, 1 to 11, are represented as folded in an inverted anticline, and broken through by a fault along the axis, the portion on the right side having been pushed up.

FIG. 30.—Inverted anticline and reversed fault.

The effect of the movement has been to make the ends of the beds on that side overlie higher beds on the other side. A shaft would thus pierce the same stratum twice. Instances of reversed faults are chiefly met with in much disturbed districts, such as mountain chains, where the rocks have been affected by great undulations and corrugations. But instances on a small scale, like that in fig. 31, may now and then be encountered even in lowland districts, where no great disturbance has taken place.

2. Faults traversing inclined strata usually group them-

selves into two series, one running in the same general direction as the dip of the strata, the other approximating

FIG. 31.—Reversed fault, Liddesdale.

to the trend of the strike. They are accordingly classified as *dip-faults* and *strike-faults*. They are not always to be sharply marked off from each other, for the dip-faults will often be observed to deviate considerably from the normal direction of dip, and the strike-faults from the prevalent strike, so that in such cases they pass into each other.

A dip-fault produces at the surface the effect of a lateral shift of the strata. This effect increases in proportion as the angle of dip lessens. It ceases altogether when the beds are vertical. Fig. 32 may be taken as a plan of a dip-fault

FIG. 32.—Plan of strata cut by a dip-fault.

traversing a series of strata which dip northwards at 25° . The beds on the east side look as if they had been pushed horizontally southwards. That this apparent horizontal displacement is due really to a vertical movement, and to the subsequent planing down of the surface by denuding agents, will be clear if we consider what must be the effect of the vertical ascent or descent of the inclined beds on one side of a dislocation. Take the bed *a* in fig. 32, and suppose it to be still unbroken by the fault. It will then run in a straight east and west line. When the fault takes place, the part on the west side is pushed up, or, what comes to the same, that on the east side is let down. A horizontal plane cutting the dislocated stratum will show the portion on the west side lying to the north of that on the east side of the fracture. The effect of denudation has usually been practically to produce such a plane, and thus to exhibit an apparently lateral shift. This surface displacement has been termed the *heave* of a fault. Its dependence upon the angle of dip of the strata may be seen by a comparison of figs. 33 and 34. In the former figure the bed *a*, once prolonged above the present surface (marked by the horizontal line), is represented as having dropped from *db* to *ec*, the angle of inclination being 25° . The heave amounts to the horizontal distance between *b* and *c*. But if the angle should rise to 60° , as in fig. 34, though the amount of throw or vertical displacement remains the same, we see that the heave or horizontal shift diminishes to about a quarter of what it is in fig. 33. This diminu-

tion would continue with every increase of inclination in the strata till among vertical beds there would be no heave at all.

FIG. 33.—Section along the line of a fault in strata dipping at 25° .

Strike-faults, where they exactly coincide with the strike, may sometimes remove the outcrop of some strata by never

FIG. 34.—Section along the line of a fault in strata dipping at 60° .

allowing them to reach the surface. Fig. 35 shows a plan of one of these faults (FF), having a downthrow to the north. In crossing the ground from north to south we pass successively over the edges of all the beds, except Nos. 3

FIG. 35.—Plan of a strike-fault.

and 4, which are cut out by the fault as shown in fig. 36, which is a section drawn across the ground at a right angle to the strike. It seldom happens, however, that such strict coincidence between faults and strike continues for

FIG. 36.—Section across the plan, fig. 35.

more than a short distance. The dip is apt to vary a little even among comparatively undisturbed strata, and every such variation causes the strike to undulate and thus to be cut more or less obliquely by the line of dislocation, which may nevertheless run quite straight. Moreover, any increase or diminution in the throw of a strike-fault will of

course have the effect of bringing the dislocated ends of the beds against the line of dislocation. In fig. 37, for in-

FIG. 37.—Plan of strata traversed by a diminishing strike-fault.

stance, which represents in plan another strike-fault, we see that the amount of throw is diminishing towards the left so as to allow lower beds to successively appear, until, at the extreme left side of the ground, the fault merely brings one part of the same bed (No. 5) against another part.

3. Their effects become more complicated where faults traverse undulating and conformed strata. Sometimes we can distinctly trace an undulation as the result of a fault. In the flat limestone beds shown in fig. 38, for example,

FIG. 38.—Curving of strata on one side of a fault.

there can be no doubt that the gentle depression from *d* to *c* would not have taken place but for the existence of the fault *ab*. But in all countries where the rocks have been thrown into folds and corrugations these structures are traversed by faults. It then often happens that the same fault appears to be alternately a downthrow on opposite sides. Let us suppose a series of gently rolling strata to be cut by a transverse fault as in the diagram in fig. 39.

FIG. 39.—Diagram of gently undulating strata cut by a fault, with alternate throw in opposite directions.

At each of the two ridges on the near side of the fault the effect is an upthrow, while in the intervening valley it is a downthrow. On the opposite side of the fault each of these effects is reversed. It rarely happens, however, that a fault makes any such visible crack at the surface. The rocks have all been worn down so much that it is usually only by careful examination of their dip that the existence of faults can be determined.

The influence of faults upon curvatures may be illustrated by a plan and sections of a dislocated anticline and syncline, which will also show clearly how the apparently lateral displacement of outcrop produced by dip-faults is due to vertical movement. Fig. 40 represents a plan of strata thrown into an anticlinal fold *AA* and a syndinal fold *SS*, and traversed by a fault *FF*, which is an upthrow to the

left hand. We have seen that a dip-fault always shifts the outcrop to the dip on the upthrow side, and this will be

FIG. 40.—An anticline (*A*) and syncline (*S*), dislocated by a fault.

observed to be the case here. Beginning at the upper side of the diagram, which may be called north, we notice that the bed *aa*, dipping towards the lower side or south at 60° , is truncated by the fault at *uv*, and that the portion on the upthrow side is shifted forwards or southward. Crossing the syncline we meet with the same bed, and as the upthrow of the fault still continues on the same side we must go some way southwards on the downthrow side before we meet with its continuation. On the southern slope of the anticline the same bed once more appears, and again is

FIG. 41.—Section along the upcast side of the fault in fig. 40.

shifted forwards as before. A section along the left or upcast side (*uv*) of the fault would give the structure represented in fig. 41; while one along the downcast side

FIG. 42.—Section along the downcast side of same fault.

(*dd*) would be as in fig. 42. These two sections clearly prove that the shifting of the outcrops at the surface can

FIG. 43.—Plan of single fault.

be simply explained by a mere vertical movement. They also show that faults which cross anticlinal and syndinal

folds narrow the anticlines but widen the synclines on the downthrow side, while they widen the anticlines and narrow the synclines on the upthrow side.

Dislocation may take place either by a single fault or as the combined effects of two or more. Where there is only one fault, as in fig. 43, one of its sides may be pushed up or let down, or there may be a simultaneous opposite movement on either side. In such cases, there must be a gradual dying out of the dislocation towards either end; and there will usually be one or more points where the displacement has reached a maximum. Sometimes, as shown in fig. 44, a fault with a considerable maximum throw (35 feet, yards, or fathoms, in the drawing) splits into minor faults at the terminations. Examples of this kind occur not infrequently in coal-work-

FIG. 44.—Plan of a fault splitting into minor faults.

ings. In other cases the offshoots take place along the line of the main fissure (fig. 45). Exceedingly complicated

FIG. 45.—Plan of main fault, with branches.

examples occur in some coal-fields, where the connected faults become so numerous that no one of them deserves to be called the main or leading dislocation.

The subsidence or elevation of a large mass or block of rock has more usually taken place by a combination of faults. If we suppose two fissures to meet at a point, as at *b* in fig. 46, and to die out respectively at *a* and *c*, the

FIG. 46.—Plan of two fissures.

intervening triangular mass *ed* may be moved upwards or downwards, or it may remain stationary while the surround-

FIG. 49.—Section of a faulted part of the thick coal of South Staffordshire.

the downthrow side, and that the wedged-shaped masses with broad bottoms have risen, while those with narrow bottoms and broad tops have sunk.

It has been already (*ante*, p. 261) pointed out that faults are traceable to the effects of elevation. The general hade or inclination of faults towards the side of downthrow was satisfactorily explained by the late Mr Jukes in the last edition of the present work.

ing ground is displaced. The maximum displacement in such an instance would be sought for towards *b*; in the direction *c* there would be no displacement at all.

It often happens that, by a succession of parallel and adjoining faults, a series of strata is so dislocated that a given stratum which may be near the surface on one side is carried down by a series of steps to some distance below. Excellent examples of these *step-faults* (fig. 47) are to be

FIG. 47.—Section of strata cut by step-faults.

seen in the coal-fields on both sides of the upper part of the estuary of the Forth. Instead, however, of having the same downthrow, parallel faults frequently show a movement in opposite directions. If the mass of rock between them has subsided relatively to the surrounding ground, they are *trough-faults* (fig. 48). They enclose wedge-shaped masses, of which the apices, formed by the junction of two

FIG. 48.—Trough-faults.

faults, point downwards. In the accompanying section (fig. 49) of a portion of the thick coal of South Staffordshire, drawn to scale by Mr Johnson of Dudley (*Records of Geol. Survey*, vol. i. part 2, p. 313), the commencement of a trough-fault is shown in the centre of the figure.

The late Mr Jukes carefully described this interesting section, and showed that the coal must once have been more arched than now, and that on the cessation of the elevatory process the fractured pieces adjusted themselves to their new position by means of dislocations. The mass of higher beds (*A*) driven as a wedge into the coal, has hindered the bed from regaining its horizontality, and at the same time has caused the adjacent parts of the coal (*BB*) to be so crushed by the enormous pressure as to have been reduced to "a paste of coal dust and very small coal" (*Memoir on South Staffordshire Coal-field*, 2d ed., p. 194).

It will be observed that the hade of the faults is towards

"Suppose," he says, "that in diagram fig. 50 we have a portion of the earth's crust, of which *AB* is the surface, and *CD* a plane acted on by some widespread force of expansion tending to bulge upwards the part *ABCD*. If then a fracture takes place along the line *EF*, it is obvious that the expanding force will, on the side of *AC*, have the widest base *CF* to act upon, while it will have a proportionately less mass to move in the part *AECF*, which grows gradually smaller towards the surface, than on the other side of the fault, where, with the smaller base *FD*, the mass *FDCE* continually grows larger towards the surface. The mass *G* will consequently be

much more easily raised into the position $AeCy$, than the mass H into the position $Df'Br'$, the elevation of which could hardly take

Fig. 50.

place without leaving a great open gap along the line of fault between FE and $f'e'$, and, moreover, without leaving the projecting piece c' overhanging without any support.

"This is yet more clearly perceptible if we suppose two such fissures, as in fig. 51, inclining towards each other, since, if we sup-

Fig. 51.

pose the included piece I to be elevated into the position indicated by the dotted lines, it becomes utterly unsupported unless we suppose huge dykes or ejections of igneous rock to issue out along each fault. But this would remove the case from the class of fractures we are at present considering."

Trough-faults offer at first some difficulty. In fig. 48, for example, it is evident that in both the wedge-shaped masses (A and B) there has been subsidence. The bed X is cut by four faults. In the space B two of these faults have towards each other, and as they have the same amount of throw the level of the bed remains unchanged on either side. In the other trough, however, the fault a has a throw twice as much as that of b which it completely cuts off. The two faults d and f' neutralize each other, and are connected with a vertical fissure without any throw. The fault a however descends with its persistent hade and dislocates the bed Z and the other strata below. Mr Jukes proposed the following satisfactory explanation of this kind of structure.

"Suppose the beds AA , BB , &c., (fig. 52) to have been formerly in a state of tension, arising from the bulging tendency of an

Fig. 52.

internal force, and one fissure, FE , to have been formed below, which on its course to the surface splits into two, ED and EC . If the elevatory force were then continued, the wedge-like piece of rock W between those two fissures, being unsupported, as the rocks on each side separated, would settle down into the gap as in fig. 53. If the elevatory action were greater near the fissure than farther from it, the single fissure below would have a tendency to gape upwards, and swallow down the wedge, so that eventually this might settle down, and become fixed at a point much below its previous relative position. Considerable friction and destruction of the rocks, so as to cut off the corner gh (fig. 53) on either side, would probably take place along the sides of the fissures, and thus widen the gap, and allow the wedge-shaped piece W to settle down still further.

"When the forces of elevation were withdrawn, the rocks would doubtless have a tendency to settle down again, but these newly-

Fig. 53.

included wedge-shaped, and other masses, would no longer fit into the old spaces, so that great compression and great lateral pressure might then take place."

In fig. 49 an excellent illustration is afforded of how an arched mass of strata has been faulted, and how trough-faults have been formed.

VI.—CLEAVAGE.

There is yet another system of divisional planes, termed *cleavage*, by which rocks are sometimes traversed. When this structure is well developed it divides a rock into parallel laminae, which run at a high angle quite independently of stratification or any other divisional planes. It is most perfect in proportion to the fineness of grain of the material in which it occurs. Hence fine argillaceous rocks show it admirably. An ordinary roofing slate may be taken as an illustration of a cleaved rock; its opposite surfaces are *cleavage-planes*, while the opposite faces of a slab of shale would be *stratification-planes*. Though most perfectly exhibited by clay-slate, cleavage occurs in other rocks, even in old lavas and tuffs, limestones, and sandstones or greywackes; but as the texture increases in coarseness the cleavage lines become more undecided and further apart. The structure may be observed to vary in distinctness in the same face of rock, being well-defined among bands of slate, but becoming faint or even disappearing in intercalated beds of sandstone or grit.

FIG. 54.—Sketch (by the late Mr Du Noyer) of a block of variegated slate from Dordvill Glen, county Wicklow. The crumpled bands mark the bedding, and the fine perpendicular striae in front are the cleavage planes; the fine lines on the darkened side merely represent shadow, and must not be taken for planes of division in the rock. It will be observed that the cleavage planes do not pass through the white bands.

The direction of cleavage usually remains persistent over considerable regions, and, as was shown by Sedgwick, corre-

sponds on the whole with the strike of the rocks. It is, however, independent of bedding. Among curved rocks the cleavage planes may be seen traversing the contortions without sensible deflexion from their normal direction, parallelism, and high angle. Mr Jukes pointed out that over the whole of the south of Ireland the trend of the cleavage seldom departs 10° from the normal direction E. 25° N., no matter what may be the differences in character and age of the rocks which it crosses. Some of the more obvious characters of cleavage are shown in fig. 54, which represents a block of cleaved variegated slate about 18 inches in height. The left side of the block which is in shadow is formed by a smooth cleavage plane, and the whole block might be split into laminae parallel to that plane as shown by the cleavage lines in front. The lines of stratification are marked by the white and dark contorted bands, the axes of which evidently correspond nearly with the direction of the cleavage. These bands are commonly marked in nature by zones of different colour, and sometimes of texture. In the present instance the white bands are more sandy than the rest of the mass, and the cleavage-planes only partially enter them. This specimen is further interesting as it bears witness by its puckered bedding to the great lateral pressure in virtue of which, as we have already seen (*ante*, p. 261), the cleavage structure has been produced.

VII IGNEOUS ROCKS AS PART OF THE STRUCTURE OF THE EARTH'S CRUST.

In this section we shall consider the part taken by igneous rocks in the architecture of the earth's crust. Their lithological differences having already been described in part II., it is their larger features in the field that now require attention,—features which in some cases can be well illustrated by reference to the action of modern volcanoes, and in other cases bring before us parts of the economy of volcanoes which can never be reached in any recent cone. A study of the igneous rocks of former ages thus serves to augment our knowledge of volcanic action.

At the outset an obvious distinction must be drawn between those igneous masses which reached the surface and consolidated there, like modern lava streams or showers of ashes, and those which we must believe never found their way to the surface but consolidated at a greater or less depth beneath it. There must be the same division to be drawn in the case of every active volcano of the present day. But we can examine only the materials which reach the surface, and we can but speculate as to the nature and arrangement of what still lies underneath. In the revolutions to which the crust of the earth has been subjected, however, the subterranean continuations of volcanic sheets have often been laid bare, and not only so, but sections have been opened into the very heart of masses which, though molten and eruptive, seem never to have been directly connected with actual volcanic outbursts. All those subterranean intruded masses, which are now revealed at the surface only after the removal of the depth of rock which once covered them, may be grouped together into one division under the names *plutonic*, *intrusive*, or *subsequent*. On the other hand, all those which came up to the surface as ordinary volcanic rocks, whether molten or fragmental, and were consequently contemporaneously interstratified with the formations which happened to be in progress on the surface at the time, may be classed in a second group under the names *volcanic*, *interbedded*, or *contemporaneous*.

It is obvious of course that these are only relative terms. Every truly volcanic mass which, by being poured out as a lava-stream at the surface, came to be regularly interstratified with contemporaneous accumulations, must have been directly connected below with molten matter which

did not reach the surface. One part of the total mass therefore would be included in the second group, while another portion, if ever exposed by geological revolutions, would be classed with the first group. Seldom, however, can the same masses which flowed out at the surface be traced directly to their original underground prolongations. It is evident that an intrusive rock, though necessarily subsequent in age to the rocks through which it has been thrust, need not be long subsequent. Its relative date can only be certainly affirmed with reference to the rocks through which it has broken. It may be older than other rocks through which it has not been intruded but which lie almost immediately above it. The probable geological date of its eruption must be decided by the evidence to be obtained from the grouping of the rocks all around. Its intrusive character can only certainly determine the limit of its antiquity. We know that it must be younger than the rocks it has invaded, how much younger must be otherwise determined. On the other hand, an interbedded or contemporaneous igneous rock has its date precisely fixed by the geological horizon on which it lies. A lava-bed or tuff interbedded among strata containing *Sphenopteris affinis*, *Lepidodendron veltheimianum*, *Lepiditæa*, and other associated fossils, would unequivocally prove the existence of volcanic action at the surface during the Lower Carboniferous period, and at that particular part of the period represented by the horizon occupied by the volcanic bed. An interbedded and an intrusive mass found on the same platform of strata would not necessarily be coeval. On the contrary, the latter, if clearly intruded along the horizon of the former, would necessarily be posterior in date. It will be understood then that the two groups have their respective limits determined solely by their relations to the rocks among which they may happen to lie.

The value of this classification for geological purposes is great. It enables the geologist to place and consider by themselves the granites, quartz-porphyrines, and other crystalline masses which, though lying sometimes perhaps at the roots of ancient volcanoes, and therefore intimately connected with volcanic action, yet owe their special characters to their having consolidated under pressure at some depth within the earth's crust; while he arranges in another series the lavas and tuffs which, thrown out to the surface, bear the closest resemblance to the ejected materials from modern volcanoes. He is thus presented with the records of hypogene igneous action in the one group, and with those of superficial volcanic action in the other. He is furnished with a method of chronologically arranging the volcanic phenomena of past ages, and is thereby enabled to collect materials for a history of volcanic action over the globe.

In adopting this classification for unravelling the geological structure of a region where igneous rocks abound, the geologist will encounter instances where it may be difficult or impossible to decide in which group a particular mass of rock must be placed. He will bear in mind, however, that after all, such schemes of classification are proposed only for convenience in systematic work, and that there are no corresponding hard and fast lines in nature. He will recognize that all crystalline or glassy igneous rocks, whether the portion visible be interbedded or intrusive, must be intrusive at a greater or less depth from the surface. Every contemporaneous sheet has proceeded from some internal pipe or mass, so that though interbedded and contemporaneous with the strata at the top, it is intrusive in relation to the strata below. But we cannot always assert that an intrusive mass must have been connected with an outflowing interbedded sheet above.

Section I.—*Plutonic, Intrusive, or Subsequent Igneous Rocks.*

Under this section we have to consider the part played

by igneous rocks which, either possessing a crystalline (sometimes glassy or felsitic) structure have been injected in a fluid or at least viscous condition into other rocks, or having been blown into fragments have consolidated in volcanic pipes. After some practice in the field the geologist learns to recognize these rocks, and to distinguish them from the similar masses which must be placed in the contemporaneous series. As a rule their crystalline texture is coarser than in that series, only in a few rare cases does a cellular or amygdaloidal character appear, and the fragmental accompaniments so characteristic of the contemporaneous sheet are only found in the actual vents of eruption. Granite, syenite, felsite, diorite, basalt, and agglomerate occur in this form.

The general law which has governed the intrusion of igneous rock within the earth's crust may be thus stated. Every fluid mass impelled upwards by pressure from below, or by the expansion of its own imprisoned vapour, has sought egress along the line of least resistance. What that line was to be has depended in each case upon the structure of the terrestrial crust and the energy of eruption. In many instances it has been determined by an already existent dislocation, in others by the planes of stratification, or by the surface of junction of two unconformable formations, or by irregular cracks and rents, or by other more complex lines of weakness. Sometimes the intruded mass has actually fused and obliterated some of the rock which it has invaded, incorporating this portion into its own substance. The shape of the channel of escape has necessarily determined the form of the intrusive rock, as the mould regulates the form assumed by a mass of cast-iron. This offers a very convenient means of classifying the intrusive rocks. According to the shape of the mould in which they have solidified, they may be arranged as—(1) amorphous masses, (2) sheets, (3) veins and dykes, and (4) necks.

I. AMORPHOUS MASSES.—These consist chiefly of crystalline coarse-textured rocks. Granite and syenite are the most conspicuous, but there are to be included also various quartz-porphyrates, felsites, diorites, &c. Where rocks occur in this form which also are found in sheets and dykes as well as contemporaneous beds, it is commonly observed that they are more coarsely crystalline in the form of amorphous masses than in any other. Doleritic rocks afford many examples of this characteristic.

Granitic Bosses.—It was once a firmly-held tenet that granite is the oldest of rocks, the foundation on which all other rocks have been laid down. This idea no doubt originated in the fact that granite is found rising from beneath gneiss, schist, and other crystalline masses which in their turn underlie very old stratified formations. The intrusive character of granite, shown by its numerous ramifying veins, proved it to be later than at least those rocks which it had invaded. Nevertheless the composition and structure of gneiss and mica-schist were believed to be best explained by supposing these rocks to have been derived from the waste of granite, and thus, though the existing intrusive granite had to be recognized as posterior in date, it was regarded as only a subsequent protrusion of the vast underlying granitic crust. In this way the idea of the primeval or fundamental nature of granite held its ground.

From what has already (*ante*, p. 258) been said regarding the fusion and consolidation of rocks, and the evidence supplied on this subject by granite itself, it will readily be understood that the first or original crust could hardly have been one of granite. That rock, so far as can be made out by careful microscopic examination, appears to have always consolidated under considerable pressure, and in the presence of superheated water and even of liquid carbonic

acid—conditions which probably never obtained at the earth's immediate surface. The original crust may have been of a glassy character like some of the vitreous lavas; but whatever it was, no trace of it has ever been or is ever likely to be found.

The presence of granite at the existing surface must in all cases be due to the removal by denudation of the masses of rock under which it originally consolidated. The fact that, wherever extensive depudation of an ancient series of crystalline rocks has taken place, a subjacent granite nucleus is apt to appear does not prove that rock to be of a primeval origin. It shows, however, that the lower portions of crystalline rocks very generally assume a granitic type, and it suggests that if at any part of the earth we could bore deep enough into the crust we should probably come to a granitic layer. That this layer, even if general round the globe, is not always of the highest geological antiquity is abundantly clear from the fact that in many cases it can be proved to be of later date than fossiliferous formations the geological position of which is known; that is, the granitic layer has invaded these formations, rising up through them, and probably melting down portions of them in its progress. This is true not only of ancient Paleozoic but of other stratified rocks of various much more recent ages. So that we must conclude that granite does not belong exclusively to the earliest nor to any one geological period, but rather that it has been formed at various epochs, and may even be forming now, wherever the conditions required for its production have existed. As a matter of fact granite occurs much more frequently in association with older and therefore lower than with newer and higher rocks. But a little reflexion shows us that this must be the case. Granite having a deep-seated origin must rise through the lower and more ancient masses before it can reach the overlying more recent formations. But many protrusions of granite would doubtless never ascend beyond the lower rocks. Subsequent denudation would be needed to reveal these protrusions, and this very process would remove the later formations and at the same time any portions of the granite which might have reached them.

Granite frequently occurs in the central parts of mountain chains; sometimes it forms there a kind of core round which the various gneisses, schists, and other crystalline rocks are arranged with more or less irregularity. More frequently it appears in large eruptive bosses which traverse indifferently the rocks on the line of which they rise. Sometimes it even overlies the schistose and other rocks, as in the Piz de Graves in the upper Engadine, where a wall-like mass of granite, with syenite, diorite, and altered rocks, may be seen resting upon schists. In the Alps and other mountain ranges it is found likewise in large bed-like masses which run in the same general direction as the rocks with which they are associated.

Many of the most characteristic features of granitic bosses can be admirably studied where the rock has risen through contorted sedimentary formations, which form undulating or hilly ground rather than mountains. The granite of the south-east and east of Iceland, the south of Scotland, and the south-west of England may be taken as illustrative examples.

In the south-east of Ireland a mass of granite 70 miles in length and from 7 to 17 in width stretches from north-east to south-west, nearly along the strike of the Lower Silurian rocks. These strata, however, have not been upraised by it in such a way as to expose their lowest beds dipping away from the granite. On the contrary, they seem to have been contorted prior to the appearance of that rock; at least they often dip towards it, or lie horizontally or undulate upon it, apparently without any reference to

movements which it could have produced. As Mr Jukes has shown, the Silurian strata are underlain by a vast mass of Cambrian rocks, all of which must have been invaded by the granite before it could have reached its present horizon. He infers that the granite must have slowly and irregularly eaten its way upward through the Silurian rocks, absorbing much of them into its own mass as it rose. For a mile or more the stratified beds next the granite have been altered into mica-schist, and are pierced by numerous veins from the invading rock. Within the margin of the granitic mass belts or rounded irregular patches of schist are enclosed; but in the central tracts where the granite is widest, and where therefore we may suppose the deepest parts of the mass have been laid bare, no such included patches of altered rock occur. From the manner in which the schistose belt is disposed round the granite, it is evident that the upper surface of the latter rock where it extends beneath the schists must be very uneven. Doubtless it rises in some places much nearer to the present surface of the ground than at others, and sends out veins and strings which do not appear above ground. If, as Mr Jukes supposes, a thousand feet of the schists could be restored at some parts of the granite belt, no doubt the belt would there be entirely buried, or, if, on the other hand, the same thickness of rock could be stripped off some parts of the band of schist, the solid granite underneath would be laid bare. The extent of granite surface exposed must thus be largely determined by the amount of denudation, and by the angle at which the upper surface of the granite is inclined beneath the schists. Where the inclination is high, prolonged denudation will evidently do comparatively little in widening the belt. But where the slope is gentle, and especially where the surface undulates, the removal for some distance of a comparatively slight thickness of rock may uncover a large breadth of underlying granite.¹

Recent observations by Professor Hull and Mr Traill of the Geological Survey have shown that in the Mourne Mountains a mass of granite has in some parts risen up through highly inclined Silurian rocks, which consequently seem to be standing almost upright upon an undelaying boss of granite. The strata are sharply truncated by the crystalline mass, and are indurated but not otherwise altered. The intrusive nature of the granite is well shown by the way in which numerous dykes of dark melaphyre are cut off when they reach that rock.²

In the Lower Silurian tract of the south of Scotland several large intrusive bosses of granite occur. The strata do not dip away from them on all sides, but with trifling exceptions maintain their normal N.E. and S.W. strike up to the granite on one side, and resume it again on the other. The granite indeed occupies the place of so much Silurian greywacke and shale. There is usually a metamorphosed belt of variable width in which, as they approach the granite, the stratified rocks assume a schistose or gneissoid character. Numerous small, dark, often angular patches or fragments of mica-schist may be observed along the marginal parts of the granite. Similar features are presented by the granite bosses of Devon and Cornwall which have risen through Devonian strata.

The manner in which some bosses of granite penetrate the rocks among which they occur strongly reminds one of the structure of volcanic necks or pipes. The granite is found as a circular or elliptical mass which seems to descend vertically through the surrounding rocks without seriously altering or disturbing them, as if a tube-shaped opening had been blown out of the crust of the earth up which the granite had risen. Several of the granite masses of the south of Scotland exhibit this character very strik-

ingly. That granite and granitoid rocks have actually been associated with volcanic action is shown by the way in which they occur in connexion with the Tertiary volcanic rocks of Skye, Mull, and other islands in the Inner Hebrides. As Mr Jukes suggested many years ago, granite or granitoid masses may lie at the roots of volcanoes, and may be the source whence the more silicated lavas, such as trachyte and laparite, proceed.³

That some granite, however, is of metamorphic origin, that is to say, has been produced by the gradual softening and recrystallization of other rocks at some depth within the crust of the earth, seems to be now satisfactorily established. Such granite may be looked upon as the extreme of metamorphism, the various schists and gneisses being less advanced stages of the process. Provided the chemical composition of the altered rock be the same as that of granite, it is not necessary that the granite resulting from its alteration should be supposed to differ in any noteworthy particular from ordinary intrusive or igneous granite. The members of the Geological Survey of Ireland have indeed distinguished two granites in Galway, one of which they regard as metamorphic, the other as igneous. The former is characterized by the occurrence of two feldspars (orthoclase and oligoclase); the latter contains only one (orthoclase). More recently, however, in the east of the country they have separated two groups of granites, of which the intrusive masses are composed of dark-coloured quartz, orthoclase, albite, and black mica (Mourne Mountains), while the metamorphic variety is formed of grey felspar, quartz, and black mica. The mineralogical composition of granite formed by the metamorphism of other and specially sedimentary rocks must necessarily vary with that of the masses out of which it has arisen. In some cases there is a regular gradation from true granite outward into the schistose and gneissose masses. But this passage need not always occur, for if the granite was subject to unequal pressure (which it assuredly would in most cases be) it would in its soft, pasty condition undoubtedly be squeezed into any rents made in the surrounding rocks, and would thus imitate exactly a truly igneous mass, which in actual fact it would then be. When a mass of granite rises through unaltered or only locally altered strata, it may fairly be assumed to be igneous and intrusive. When, on the other hand, it is intimately associated with extensive masses of schist and gneiss, many of which can only be distinguished from it by their foliated structure, its metamorphic origin may at least be strongly suspected. Fundamentally, indeed, igneous and metamorphic granite seem to be due only to different modifications of the same subterranean processes. A mass of originally sedimentary rocks may be depressed to a depth of several thousand feet within the earth's crust, subjected there to vast pressure and considerable heat in presence of interstitial water or steam, and may thus be metamorphosed into crystalline schists. A portion of this mass, undergoing extreme alteration, may so completely lose all trace of its original fissile structure as to become amorphous crystalline granite, some of which may even be thrust as veins into the less highly changed parts above and around. One stage further would bring before us a connexion opened between the surface and such a deep-seated granitic mass, and the consequent ascent and outburst of acid lavas and their fragmental accompaniments.

Amorphous Masses of Diorite, &c.—On a smaller scale usually than granite, other crystalline rocks assume the condition of amorphous bosses. Syenite, diorite, quartz-porphry, and members of the basalt family have often been erupted in irregular masses, partly along fissures, partly along the bedding, but often involving and appar-

ently melting up portions of the rocks through which they have made their way. Such bosses have frequently tortuous boundary-lines, since they send out veins into or cut capriciously across the surrounding rocks. In Wales, as shown by the maps and sections of the Geological Survey, the Lower Silurian formations are pierced by huge bosses of different crystalline rocks, mostly included under the old term "greenstone," which, after running for some way with the strike of the strata, turn round and break across it, or branch and traverse a considerable thickness of stratified rock. In central Scotland numerous masses of dolerite and quartziferous diabase have been intruded among the Lower Carboniferous formations. One horizon on which they are particularly abundant lies about the base of the Carboniferous Limestone series. Along that horizon they rise to the surface for many miles, sometimes ascending or descending in geological position, and breaking here and there abruptly across the strata. There can be little doubt that they have actually melted down some parts of the stratified rocks, particularly the limestone. Considerable petrographical differences occur among them which may perhaps be in some measure due to the incorporation of such extraneous material into their mass. Gaps occur where these intrusive rocks do not rise to the surface, but as they resume their position again not far off, it may be presumed that they are really connected under these blank intervals.

The amount and nature of the alteration produced on contiguous rocks by the invasion of an intrusive boss vary necessarily with the character and bulk of the igneous mass, as well as with the susceptibility of the surrounding rock to metamorphism. Induration is generally traceable; shales are hardened into porcellain, jasper, Lydian-stone, or some other flinty argillaceous rock. Sandstones are converted into a kind of lustrous quartz-rock. Limestones are made to assume a granular or crystalline texture, passing into marble or sometimes into dolomite. Under favourable conditions crystals of garnet, analcime, pyrite, and other minerals are developed in the surrounding altered rock.

There can be little doubt that, though the portions of these rocks now visible consolidated under a greater or less depth of overlying rock, they must in many cases have been directly connected with superficial volcanic action. Some of them may have been underground ramifications of the ascending molten rock which poured forth at the surface in streams of lava. Others may mark the position of intruded masses which were arrested in their ascent in the unsuccessful attempt to open a new volcanic vent.

II. SHEETS.—These are masses of crystalline rock which have been intruded as sheets between other rocks, and now appear as more or less regularly defined beds. In almost all cases it will be found that these intrusions have taken place between the planes of stratification. The ascending mass of molten matter, after breaking across the rocks, or rather after ascending through fissures either previously formed or opened at the time of the outburst, has at last found its path of least resistance to lie along the bedding planes of the strata. Accordingly it has thrust itself between the beds, raising up the overlying mass and solidifying as a nearly or exactly parallel cake or bed.

It is evident that one of these intercalated intrusive sheets of igneous rock must present such points of resemblance to a truly contemporaneous bed of lava as to make it occasionally a somewhat difficult matter to determine its true character, more especially when, owing to extensive denudation, only a small portion of the rock can now be seen. The following characters mark intrusive sheets, though they must not be supposed to be all present in every case. (1.) They do not rigidly conform to the bedding, but

sometimes break across it and run along on another platform. (2.) They catch up and involve portions of the surrounding strata. (3.) They are commonly most close-grained at their upper and under surfaces, and most coarsely crystalline in the central portions. (4.) They are very rarely cellular or amygdaloidal. (5.) The rocks both above and below them are usually hardened and otherwise more or less altered.

Many of the older volcanic rocks occur in this form, as feldstone, quartz-porphyr, diorite, melaphyre, diabase, dolerite, basalt, and others. The remarks above made regarding the connexion of intrusive bosses with volcanic action may be repeated with even greater definiteness here. Intrusive sheets abound in old volcanic districts intimately associated with dykes and surface outflows, and thus bringing before our eyes traces of the underground mechanism of the volcanoes.

The same kinds of alteration may be observed along the line of junction of intrusive sheets with the adjacent rocks as in the case of amorphous masses; but as the boundary lines are often very sharply defined they present the process of alteration in a more generally accessible and interesting form. Sandstone, for example, besides being indurated and acquiring the distinct lustre of quartzite, may occasionally be seen to possess a distinctly prismatic structure—the prisms or columns diverging at right angles to the line of junction with the igneous rock. Even microscopic black microlites, like those which occur in basalt-rocks, have been detected in altered sandstone, in the minute fissures of which they may be supposed to have been sublimed from the molten injected mass. Argillaceous rocks are commonly converted into hard flinty textures to which the names of flinty-slate, Lydian-stone, jasper, and porcellanite have been applied. Coal-seams when invaded by intruded sheets of igneous matter assume different aspects according to the thickness and nature of the invading sheet, the depth of the coal-seam, and probably to other less easily recognizable causes. In some cases the coal has been fused and has acquired a blistered or vesicular texture, the gas cavities being either empty or filled with mineral matter such as calcite. In other cases it has nearly disappeared, the remaining portion being a black soot or ash. In others it has become hard and brittle, and has been converted into a kind of anthracite or "blind-coal," owing to the loss of its more volatile portions. In the Ayrshire coal-fields the coal seams have sometimes become beautifully columnar owing to the intrusion of a sheet of basalt along them. The hexagonal and pentagonal columns diverge like rows of stout pencils from the surfaces of the basalt. In one coal-field of that county a seam of coal has been converted into graphite. The accompanying section (fig. 55) by the late

FIG. 55.—Sheets and strings of intrusive rock in the Tan-yard Coal, South Staffordshire.

Mr Jukes represents one of the numerous sheets of "white rock" intruded into the South Staffordshire coal-field. The horizontal distance shown in this section is more than 100 yards. The coal (c) resting on sandstone (e) is traversed by irregular strings and sheets (a) of what the miners term "white-rock," which proceed from the large basalt masses of the district. The coal has there become dull and anthracitic, and is not worth being extracted.

When a coal-field is much invaded by igneous rocks the seams of coal are usually found to have suffered more than the other strata, not merely because they are specially liable to alteration from the proximity of heated surfaces, but

because they have presented lines of more easy escape for the igneous matter pressed from below. The molten rock has very generally insinuated itself along the coal-seams, sometimes taking the lower, sometimes the upper surface, and not infrequently forcing its way along the centre.

In the destruction or alteration of coal and bituminous shales a process of subterranean distillation must often have been set in progress. The gases evolved would find their way to the surface through joints and pores of the overlying rock. The liquid products, on the other hand, would be apt to collect in fissures and cavities. In central Scotland, where the coal-fields have been so abundantly pierced by igneous masses, petroleum and asphaltum are of frequent occurrence in many districts, sometimes in chinks and veins of sandstones and other sedimentary strata, sometimes in the cavities of the igneous rocks themselves.

It is a remarkable fact that, striking as is the change produced by the intrusion of basalt into coals and bituminous shales, it is hardly more conspicuous than the alteration effected on the invading masses themselves. A compact crystalline black heavy basalt or dolerite, when it sends sheets and veins into a coal or highly carbonaceous shale, becomes yellow or white, earthy, and friable, loses weight, ceases to have any apparent crystalline texture, and in short passes into what any observer would at first unhesitatingly pronounce to be a mere clay. It is only when the distinctly intrusive character of this substance is recognized in the veins and fingers which it sends out, and in its own irregular course in the coal, that its true nature is made evident (see fig 55). Microscopical examination shows that this "white-rock" or "white-trap" is merely an altered form of basalt, wherein the felspar crystals, though much decayed, can yet be traced, the augite, olivine, and magnetite being more or less completely changed into a mere pulverulent earthy substance. A specimen of this altered rock was analysed by Mr Henry with the following results.—

Silica	88 830
Alumina	13 250
Lime	3 925
Magnesia	4 180
Soda	0 971
Potash	0 422
Protoxide of iron	13 630
Peroxide of iron	4 335
Carbonic acid	9 920
Water	11 010
	100 073

It is evident that most of the alkalis and much of the silica have been removed, and that most of the iron exists as carbonate of the protoxide.

In connexion with the alteration produced by igneous sheets upon their contiguous stratified rocks, reference may here be made to the lithological differences traceable within the igneous masses. The close grain already referred to as characteristic of the upper and under portions of an intrusive sheet evidently depends upon more rapid cooling towards the surface of contact with the adjacent cold rocks. When thin slices of these marginal parts are placed under the microscope, they sometimes show abundant black microlites which disappear as the rock is traced away from the margin. They may be regarded as incipient stages in the crystallization of the magnetite, arrested in their development by the rapid consolidation of the outer parts of the rock. In the central portions they have had an opportunity of coalescing into octahedral or groups of definite isometric crystals. A series of sections of a rock, from the outer edge where the arrested crystallites occur to the centre where definitely-built crystals appear, brings in this way before us a history of the stages in the consolidation of the mass.

But considerable differences in composition may also be

detected in different portions of the same intrusive sheet. A rock which at one place gives under the microscope a coarsely crystalline texture with the petrographical elements of dolerite will at a short distance show abundant orthoclase and free quartz—minerals which do not belong to normal dolerite. These differences, like those above referred to as noticeable among amorphous bosses, seem too local and sporadic to be satisfactorily referred to original differences in the composition of various parts of the molten mass, or to segregation by gravitation or otherwise. They suggest rather that the great intrusive sheets, in their passage through the rocks underneath, have here and there involved and melted down portions of these rocks, and have thus acquired locally an abnormal composition.

III. VEINS AND DYKES.—Veins of igneous rock may occur indifferently in igneous, aqueous, or metamorphic rocks. They may range in diameter from mere thread-like filaments up to huge bands many feet or yards broad. In regard to their origin they may be grouped into two series—(1) veins of segregation, and (2) veins of intrusion.

Veins of Segregation.—These include most of what were formerly and not very happily termed "contemporaneous veins." They are peculiar to crystalline rocks. They abound in many granites, likewise in some gneisses and schists. They may not infrequently be observed in sheets of diorite, dolerite, and diabase. They run as straight, curved, or branching ribands, seldom exceeding a foot in thickness. Most frequently they are finer in texture than the rock which they traverse, though now and then the reverse is the case, more especially in granite. Close examination of them shows that they are not sharply defined by a definite junction line with the enclosing rock, but that on the contrary they are welded into that rock in such a way that they cannot easily be broken along the plane of union. This welding is found to be due to the mutual protrusion of the component crystals of the vein and of the surrounding rock—a structure sometimes admirably revealed under the microscope. Veins of this kind are evidently to be referred to the earliest condition of the rocks in which they occur. They point to some process, still unexplained, whereby into rents formed in the deeply buried, and at least partially consolidated or possibly colloid, mass there was a transfusion or exsmosis of some of the crystallizing minerals.

Veins of Intrusion.—These are portions of once-melted or at least pasty matter which have been injected into rents of previously solidified rocks. When traceable sufficiently far, they may be seen to swell out and merge into their large parent mass, while in the opposite direction they may become attenuated into mere threads. Sometimes they

FIG. 55.—INTRUSIVE IGNEOUS ROCK

run for many yards in tolerably straight lines, and when this takes place along the stratification they look like beds. At these parts, they are of course really intrusive sheets. But they may frequently be found to start suddenly upward or downward, and to break across the bedding in a very irregular manner. In fig. 56 *t* represents an intrusive

igneous rock running through horizontal strata. If we saw merely the horizontal portion below or above, the really igneous and intrusive nature of the rock might escape us, but the intermediate connecting vein makes its character at once apparent.

No rock exhibits so admirably as granite the varieties assumed by veins. In many cases the veins which traverse the granite itself must be regarded as segregation or infiltration veins, as already described. But where they proceed from the granite, and traverse surrounding rocks, they are probably in most cases intrusive, though where granite and highly granitic gneiss are in contact we may conceive that some of the veins traversing both rocks may be segregation veins. Most large masses of granite send veins into the surrounding rocks. Frequently the veins so abound as to form a complicated net-work. They vary in breadth from several feet or even yards down to fine filaments at the ends of the smaller branches. They frequently cross each other, not only outside of the granite mass, but even within it. They vary much in texture and in composition. Sometimes they are coarsely crystalline; but probably most of the veins of this kind are due rather to segregation than intrusion. Most frequently granite veins traversing granite are finer-grained than the main mass. Veins which are clearly intrusive are not only finer in grain than the parent granite, but sometimes present considerable differences in mineralogical composition. The mica, for example, may be reduced to exceedingly minute and not very abundant flakes, and may almost disappear. The quartz also occasionally assumes a subordinate place, and the rock of the veins passes into *eurite*, *elvanite*, or one of the varieties of *porphyry*.

The rocks surrounding a granite mass and traversed by granite veins are almost always more or less metamorphosed in a belt varying in breadth from a few yards up to a mile or more. It is in this zone that the granite veins typically occur. The altered rocks have assumed the characters of *gneiss*, *mic-schist*, or other metamorphic product, but resume their usual condition as we trace them away from the granite. Curious angular portions of them may often be observed within the granite veins and in the main granite mass. In Cornwall the granite and surrounding slates are traversed by veins of quartz-porphyry termed *elvans*, which are most numerous near the granite. They vary in width from a few inches or feet to 50 fathoms, their central portions being commonly more crystalline than the sides. In the great granite region of Leicester Mr Jukes traced some of the *elvans* for several miles running in parallel bands, each only a few feet thick, with intervals of 200 or 300 yards between them. Many of the other intrusive rocks likewise present the phenomena of veins, diorite, diabase, melaphyre, and basalt furnish numerous illustrations.

Dykes are wall-like masses of igneous rock, filling vertical or highly-inclined fissures. They differ therefore from veins in the greater parallelism of their sides, their verticality, and their greater regularity of breadth and persistence of direction. They present as great a variety of thickness as that which is shown by veins. Sometimes they occur as mere plates of rock not more than an inch or two in thickness; at other times they attain a breadth of ten or twelve fathoms. The smaller or thinner dykes can seldom be traced more than a few yards; but the larger examples may be followed sometimes for miles. Thus in the south of Scotland a remarkable series of basalt-dykes can be traced across all the geological formations of that region and even across powerful faults. They run parallel to each other in a general north-west and south-east direction for distances of 20 and 30 miles. A remarkable dyke crosses the north of England from the coast of Yorkshire for fully 60 miles inland.

The name dyke is applied to these masses of igneous rock on account of their resemblance to walls (*Scotce*, dykes). Their sides are often as parallel and perpendicular as those of a piece of masonry. Moreover, the resemblance to human workmanship is sometimes brought out still more by the numerous joints which, intersecting each other along the face of a dyke, remind us of well-fitted masonry. Where the surrounding rock has decayed, the dykes may be seen projecting above the ground exactly like walls; indeed in many parts of the west of Scotland they are made use of for enclosures. The material of the dykes has in other cases decayed, and deep ditch-like hollows are left to mark their sites. The coast-lines of many of the Inner Hebrides and of the Clyde Islands furnish numerous admirable examples of both kinds of scenery.

While veins have been injected into irregular branching cracks, dykes have been formed by the welling upwards of liquid rock in vertical or steeply inclined fissures. Sometimes the line of escape has been along a fault. In Scotland, however, which may be regarded as a typical region for this kind of geological structure, the vast majority of dykes rise along fissures which have no throw, and are therefore not faults. On the contrary the dykes may be traced across some of the largest faults in the midland counties.

While the term dyke might be applied to some of the wall-like intrusions of porphyry, *elvanite*, and even of granite, it is more typically illustrated among the *aeugitic* igneous rocks, such as basalt, diabase, &c., though also among diorites, porphyries, pitchstones, &c. The central parts of a dyke are usually most crystalline. Towards the margin the grain becomes finer, and even sometimes passes into a vitreous condition. Many of the basalt dykes in different parts of Scotland are coated along the sides with a film or crust of black vitreous tachylite. Lines of amygdaloidal kernels may not infrequently be traced along the centre of a dyke.

When the rock on one side is freshly stripped off, the dyke is usually observed to present a system of polygonal jointing. The joints start from each face or cheek, and either go right across to the opposite side, or branch and lose themselves about the centre. They thus divide the dyke into irregular prisms which, when the dyke is vertical, lie of course in a horizontal position, whence they depart in proportion as the dyke is inclined. Occasionally the prisms are as well-formed as in any columnar bed of basalt. A less prominent set of joints runs parallel with the two cheeks of a dyke.

There is usually some alteration of the stratified rocks in contact with a dyke, but the nature and amount of the change vary within a wide range. The most sensitive material to this influence is undoubtedly coal. A seam of coal 6 or 8 feet in thickness may be observed to grow dull and brittle at a distance of 50 yards from a large dyke, becoming what is termed "blind coal," as it then burns without flame. Still nearer to the intrusive mass the coal passes into a kind of pyritous cinder scarcely half the original thickness of the seam. At the actual contact with the dyke it becomes by degrees a kind of caked soot not more perhaps than a few inches thick. Sandstones are hardened into a kind of lustrous quartzite, and sometimes made columnar, shales into flinty slate or porcellanite; limestones are occasionally rendered crystalline and even dolomitic. Occasionally a segregation of new minerals has taken place in the rocks adjoining a dyke. But cases are by no means infrequent where dykes have produced little or no appreciable change upon the contiguous rocks.

IV. NECKS.—Under this term are included the filled-up pipes or funnels of former volcanic vents. Every series of volcanic sheets poured out at the surface must have been

connected with one or more orifices which, on the cessation of the eruptions, would remain more or less completely filled with lava or with fragmentary matter. But unless subsequent denudation should remove the overlying cone and its surrounding piles of lava and tuff, these vents must remain buried under the materials which came out of them. So extensive, however, has been the waste of the surface in many old volcanic regions that the sites of the vents have been laid bare. In the study of these we have before us some of the more deep-seated phenomena of volcanic action never to be seen in any modern volcano.

A neck is of a circular or elliptical, but occasionally of a more irregular branching form. It varies in diameter from a few yards up to a mile, or even more. It descends into the earth perpendicularly to the stratification of the formation to which it belongs. Thus, if a neck was formed and filled up during the accumulation of a certain group of strata, it would rise on the whole vertically through these strata, and its ejected lava or tuff would spread out conformably among them. Should the rocks be subsequently tilted the neck would of course be thrown out of the vertical. As a rule, however, the vertical descent of the necks into the earth's crust has been comparatively little interfered with.

The materials filling up ancient volcanic orifices are sometimes crystalline, sometimes fragmental. The neck may be occupied by some form of lava, as felsstone, quartz-porphry, diabase, porphyry, basalt, or by the fragmentary materials which fell back into the throat of the volcano and finally solidified there; or by both kinds of rock combined. Among the Palaeozoic volcanic districts of Britain the necks not infrequently are filled with some siliceous crystalline rock, such as a quartz-porphry or felsstone, even where the surrounding lavas are basic. Necks of agglomerate and fine tuff abound among the Carboniferous and Permian volcanic regions of Scotland.

The fragmentary materials consist mainly of different lava-form rocks imbedded in a gravelly *peperino*-like matrix of more finely comminuted debris of the same rocks, but they also contain, sometimes in abundance, fragments of the strata through which the necks have been drilled. Pieces of fine stratified tuff not infrequently appear in the agglomerates. This fact, coupled with the not uncommon occurrence of a tumulous fractured and highly-inclined bedding of the materials in the necks appears to show that the pipes were partly filled up by the subsidence of the tuff consolidated in beds within the crater and at the upper part of the funnel. Veins of basalt abound in many of the necks of Carboniferous age in central Scotland.

The strata round a neck are usually somewhat hardened. The sandstones have acquired sometimes a vitreous lustre; argillaceous beds have been indurated into porcellanite; coal-seams have been burnt and rendered unworkable. These changes may be due partly to the heat of the ascending column of molten rock or ejected fragments, partly to the ascent of heated vapours, even for a long time subsequently to the volcanic explosions. Proofs of a metamorphism probably due to the latter cause may sometimes be seen within the area of a neck. It is where the altered materials are of a fragmentary character that the nature and amount of this change can be best estimated. What was originally volcanic dust has been converted into a crystalline and even porphyritic mass, through which, however, the likewise intensely altered blocks interspersed through the agglomerate are still recognizable. Such blocks as, from the nature of their substance, must have offered most resistance to change,—pieces of sandstone or quartz, for example,—stand out prominently in the altered mass, though even they have undergone more or less modification, the sandstone being converted into vitreous quartz-rock.

Section II.—Volcanic, Interbedded, or Contemporaneous Igneous Rocks.

The rocks comprised in this section have all been ejected to the surface like the lava-streams and showers of ashes of modern volcanoes. It is evident that on the whole they must agree in lithological characters with those rocks, described in the previous section, which have been extravasated by volcanic efforts though not quite reaching the surface. Yet they have some well-marked general characters, of which the most important may be thus stated. (1.) They occur as beds or sheets which conform to the bedding of the strata among which they are intercalated. (2.) They do not break into or involve portions of the overlying beds. (3.) The upper and under portions of the lava sheets present commonly a scoriaeous or vesicular character, which may even be found extending throughout the whole of a sheet. (4.) Beds of tuff are frequently interstratified with the crystalline sheets.

I. CRYSTALLINE.—While the underground course of a protruded mass of molten igneous rock has widely varied according to the shape of the channel through which it proceeded, and in which, as in a mould, it solidified, the behaviour of the rock, once poured out at the surface, has been much more uniform. As in modern lava, the erupted rock has rolled along, varying in thickness and other minor characters, but retaining the broad general aspect of a bed or sheet. A comparison of such a bed with one of the intrusive sheets already described shows that in several important respects they differ from each other. An intrusive sheet is closest in grain near its upper and under surfaces. A contemporaneous bed or true lava-flow, on the contrary, is there usually most open and scoriaeous. In the one case we rarely see vesicles or amygdulæ, in the other they often abound. However rough the upper surface of an interbedded sheet may be, it never sends out veins into nor encloses portions of the superincumbent rocks, which, however, sometimes contain portions of it, and wrap round its hummocky irregularities, as shown in fig 57. Occasion-

FIG 57.—Section of the upper surface of an interbedded sheet S, showing how its true courses are wrapped round and covered by the sedimentary rock S.

ally it may be observed to be full of rents which have been filled up with sandstone or other sedimentary material. In these cases we see that the lava cracked in solidifying, and that sand was washed into the fissures where it consolidated. The amygdaloidal cavities throughout an interbedded sheet, but more especially at the top, may often be noticed with an elongated form, and even pulled out into tube-like hollows in one general direction, which was obviously the line of movement of the yet viscous mass.

Some kinds of rock when occurring in interbedded sheets are apt to assume a system of columnar jointing. Basalt in particular is distinguished by the frequency and perfection of its columns. The Giant's Causeway and the cliffs of Staffa, of Ardun in Mull, and of Loch Staffa in Skye are well-known examples. The columns are set perpendicularly to the two cooling surfaces, that is, to the top and bottom of the bed. Any inclination from the horizontal in the disposition of the bed will cause a corresponding departure from the vertical on the part of the columns. Sometimes the columns are arched or curved, as in the Clam-shell Cave, Staffa.

A single interbedded sheet of crystalline rock seldom occurs by itself without any other volcanic accompaniment. It is usually associated at least with bands of tuff showing that the emission of lava was not unattended with fragmentary ejections. In the majority of cases it will be found to form part of a series of interbedded sheets with intercalated tuffs. Vast piles of such consecutive flows, reaching a total depth of several thousand feet, remain to witness the energy of former volcanic vents.

II. FRAGMENTAL.—The rocks embraced under this term include all the fragmentary volcanic ejections which enter into the composition of the earth's crust, from the coarsest agglomerate to the finest tuff. They differ in lithological character, according to the nature of the lavas with which they are associated and from which they have been derived. Thus in a region of trachyte-lavas, we have trachyte-tuffs, trachyte-breccias, in one of basalts, we find basalt-breccias, basalt-agglomerates, basalt-tuffs; in one of obsidians, we meet with pumiceous tuffs and breccias. The fragmentary matter has been ejected from volcanic vents, and has fallen partly back into the funnels of discharge, partly over the surrounding area. It is therefore apt to be more or less mingled with ordinary sedimentary detritus. We find it indeed passing insensibly into sandstone, shale, limestone, and other strata.

Great differences occur in the texture of fragmental rocks even in the same volcanic districts. They are often coarse and tumulous at or near the vents, and fine-grained at a distance. Alternations of gravely *peperino*-like tuff with a very fine-grained "ash" may frequently be observed. Large blocks of lava-form rock, as well as of the strata through which the volcanic explosions have taken place, occur in the tuffs of most old volcanic districts.

It has been already pointed out that agglomerate and tuff are not infrequently to be met with occupying the sites of the vents of eruption. Their most common disposition, however, is in beds either alone or associated with interbedded lavas. Masses of fine or gravely tuff several hundreds of feet in thickness, without the intervention of any lava-bed, may be observed in the volcanic districts of the Old Red Sandstone and Carboniferous systems in Scotland. On the other hand, in these same areas thin seams of tuff may be seen interlaminated with ordinary sandstone, shale, or limestone. In the one case we have evidence of long-continued and powerful volcanic action, during which fragmentary materials were showered out and spread over the water-basins to the exclusion of ordinary sediment. In the other we have proof of feeble intermittent volcanic explosions, whereby light showers of dust were discharged, which settled down quietly amidst the sand, mud, or limestone accumulating around at the time. Under these latter circumstances tuffs often become fossiliferous, they enclose the remains of such plants and animals as might be lying on the lake-bottom or sea-floor over which the showers of volcanic dust fell, and thus they form a connecting link between aqueous and igneous rocks.

VIII.—METAMORPHIC ROCKS AS PARTS OF THE ARCHITECTURE OF THE EARTH'S CRUST.

In part ii. (*ante*, p. 235) some account has been given of the composition of certain foliated rocks frequently met with in the central portions of mountain chains and elsewhere, lying beneath geological formations of high antiquity. In part iii., in the discussion of the hypogene causes of change within the earth's crust, reference was again made to these rocks, and they were alluded to as examples of the effects of subterranean processes altering the original character of large mineral masses (*ante*, p. 263). They were there cited as *metamorphic* rocks, but their characters

as integral parts of the earth's crust were reserved for discussion in the present part of this article.

At the outset some caution must be employed as to the exact meaning in which the terms "metamorphism" and "metamorphosed" are employed. In a certain sense it may be said that all or nearly all rocks have been metamorphosed, since it is exceptional to find any, at least among such as are not in a geological sense of modern date, which do not show, when closely examined, proofs of having been altered by the action of percolating water or other daily acting metamorphic agent. Even a solid crystalline mass which, when viewed on a fresh fracture with a good lens, seems to consist of unchanged crystalline particles will usually betray under the microscope unmistakable evidence of alteration. And this alteration may go on until the whole internal organization of the rock has been readjusted, though the external form may still remain such as hardly to indicate the change, or to suggest that any new name should be given to the recomposed rock. Among many igneous rocks, particularly the more basic kinds, as basalts, diorites, olivine rocks, &c., metamorphism of this kind may be studied in all its stages.

But it is not to alteration of this nature, effected at the surface by meteoric water, that the term metamorphism is properly applied. That word is reserved for the process of subterranean change above treated of (*ante*, p. 258), whereby a more or less complete transformation has been effected throughout vast mineral masses which, while undergoing crystalline rearrangement, have usually suffered simultaneously enormous compression. Gneiss, mica-schist, and the other schistose or foliated rocks are typical examples of the results of this metamorphic process.

Three antagonistic opinions are at present entertained regarding the origin of these rocks. Some geologists regard the crystalline schists as plutonic rocks representing the early cooled crust of the earth, and suppose that a similar schistose structure has occasionally been superinduced by plutonic action on later sedimentary formations. Again, by some recent writers the Wernerian notion of chemical precipitation has been revived, and the idea of metamorphism has been discarded. These authors suppose that the schistose rocks, in common with many pyroxenic and hornblende rocks (diabases, diorites, &c.), as well as masses in which serpentine, talc, chlorite, and epidote are prevailing minerals, have been deposited "for the most part as chemically-formed sediments or precipitates, and that the subsequent changes have been simply molecular, or at most confined in certain cases to reactions between the mingled elements of the sediments, with the elimination of water and carbonic acid." To support this view, it is necessary to suppose that the rocks in question were formed during a period of the earth's history when the ocean had a considerably different relative proportion of mineral substances dissolved in its waters, and consequently that they must be assigned to a very early geological period, anterior indeed to what are usually termed the Palæozoic ages. And it becomes further needful to discredit the belief that any gneiss or schist can by possibility belong to one of the later stages of the geological record. The more thorough-going advocates of the pristine or "cosmic" date and original chemical deposition of the so-called "metamorphic" rocks do not hesitate to take this step, and endeavour, by ingenious explanations, to show that the majority of geologists have mistaken the geological structure of the districts where these rocks have been supposed to be metamorphosed equivalents of what elsewhere are Palæozoic, Secondary, or Tertiary strata.¹ Prevalent opinion supports the third or metamorphic theory, according to which the schistose rocks

¹ See Sterry Hunt's *Chemical Essays*, p. 283 *sq.*

are held to be crystalline transformations of ordinary sedimentary strata. The problem whether or not certain masses of gneiss or schist represent equivalent unaltered sedimentary rocks of other districts is mainly one of structural geology. It must be decided by the geologist rather than the chemist. It has been answered in the affirmative by the great majority of stratigraphical geologists all over the world. We may not be entitled to assert that every mass of gneiss or schist is a metamorphosed sedimentary rock. Possibly some foliated rocks of extreme antiquity may have originated directly from chemical precipitation. But when it can be shown that ordinary stratified rocks have been converted into schist and gneiss, it seems permissible to hold that all such rocks have had a similar origin, at least until good reasons can be adduced against that view.

It is evident that if the so-called metamorphic rocks can anywhere be seen to graduate into unaltered strata, it is there that they ought to be specially studied, and that light may be expected to be cast on their origin and history. It is customary to speak of metamorphism as being either local or regional, that is, being confined to one limited portion of a mass of rock, or as extending throughout the whole of the rock and over wide districts. It is doubtless from the first of these developments that we may hope to learn most regarding metamorphic changes.

Local (Contact) Metamorphism.—The simplest and most obvious examples of this kind of alteration occur where a mass of igneous rock has invaded sedimentary strata, which have in consequence been affected in lithological character along the margin of contact with the intrusive rock. Allusion has already been made to changes of this kind effected by intrusive sheets and dykes, and likewise traceable round the edges of ancient volcanic vents. Sandstones are converted into a lustrous crystalline quartz-rock; shales and argillaceous strata are indurated into porcellanite, jasper, flinty-slate, or some analogous product. Limestones are made crystalline; coals are charred, turned into anthracite, and sometimes even into graphite. These metamorphisms extend to very variable distances from the intrusive rock. Sometimes they are scarcely perceptible at all, and disappear within a space of a few inches. In other cases they extend for some feet, and in the case of some coal-seams even to 50 yards or more.

It is around bosses of granite however that the most marked examples of local metamorphism can be observed. On a previous page some account has been given of the way in which the Silurian rocks of Ireland and the south of Scotland are pierced by large masses of granite, and how, as they approach the granite even at a horizontal distance of a mile or more, they begin to assume a micaceous foliated texture which becomes more and more marked until, along the margin of the granite, they pass into true mica-schist and gneiss. The identity of origin between these schistose masses and the greywackes and shales beyond the metamorphic zone does not admit of any question. The unaltered rocks can be followed step by step into and through the stages of alteration, until they are found to have acquired the genuine gneissic or schistose structure. Moreover, it may be observed that all the bands of sedimentary rock do not give rise to the same kinds of metamorphic products. Some kinds of strata are more prone to alteration than others, and give rise to more perfect schists. In the south of Scotland, for example, certain greywackes and grits formed of a granular mixture of quartz-sand, feldspar, clay, and various decomposition products have been metamorphosed into perfect mica-schist, while some bands of black anthracitic and graphitic shale have merely been intensely indurated and shattered. Many districts in Scotland, in Ireland, in the lake country of England, and in Wales might

be cited as furnishing examples of this gradual conversion of ordinary sedimentary rocks into true schists.

Regional Metamorphism.—If then it can be proved that over limited areas thoroughly foliated rocks have been produced by the transformation of ordinary sedimentary strata, a presumption is established in favour of a similar mode of origin for foliated rocks elsewhere and over wider regions. There occur many vast spaces of the earth's surface occupied by foliated rocks. In Finland, Scandinavia, and the Scottish Highlands tracts many thousands of square miles in extent consist of gneiss, mica-schist, hornblende-rock, and other members of the same great family of rocks. A large portion of British North America lies upon similar mineral masses. Rocks of this type commonly rise also along the core of great mountain ranges, as in the Alps and in the Rocky Mountains. If these rocks which cover such vast areas were originally ordinary sedimentary rocks, they must have been metamorphosed, not by mere local protrusions of igneous matter, but by some general process.

Gradations of Metamorphism.—We have seen above that the nature and extent of the alteration experienced by rocks have been regulated, not merely by the vigour of the metamorphic process, but by the composition and structure of the rocks themselves. A siliceous sandstone, for instance, containing little or no aluminous or other admixture, seems to be capable of retaining much of its original character, while surrounding or intercalated less purely quartzose beds have been completely changed. It is converted into quartz-rock, but still shows the rounded quartz grains of the original sand. In proportion as the sand has been mixed with clay it has produced a rock more susceptible of change. The argillaceous (or magnesian) cement has been attacked, and in the process of change the quartz-sand has been affected. Mica in one or other of its various forms, aluminous or magnesian, has very generally appeared, and in proportion to its development has the foliated structure been made apparent. Hence we may obtain every gradation from a quartz-rock or grit into a true mica-schist or gneiss.

Production of Foliation.—The term "foliation" means the separation of a rock into approximately parallel or lenticular crystalline layers or folia of different mineral composition. It implies a segregation and crystallization of mineral matter along distinct planes. Those who maintain the original chemical precipitation of the most ancient gneisses and schists believe that the folia mark the stratification of the successive layers of deposit. Those, on the other hand, who hold that all the schistose rocks about the origin of which any satisfactory conclusion can be reached were originally mechanical sediments of ordinary kinds, regard the folia as coincident generally with the stratification of these sediments.

The folia of a gneiss or schist are crystalline aggregates which along their planes of mutual contact are as it were welded or felted into each other by the interlacing of their several component crystals. They are destitute, as a rule, of the parallelism, flatness, and persistence so characteristic of stratification. On the contrary they are apt to swell out into thick concretionary aggregations and to die out rapidly; they exhibit a wavy, crumpled, or puckered arrangement traceable in vast folds on the side of a mountain, and yet descending even to such minute corrugation as can only be detected by the microscope.

Foliation occurring in altered sedimentary rocks must be due to a crystallization and rearrangement of the chemical constituents of these rocks along certain lines. On a former page (*ante*, p. 263) it was pointed out that this kind of metamorphism would as a rule proceed along the lines of stratification. Doubtless in the vast majority of cases

the planes of foliation are coincident with the general direction of this stratification. The metamorphic rocks of the Scottish Highlands furnish admirable proofs of this fact. Bands of quartz-rock and schist alternate with each other and with zones of limestone, precisely as beds of sandstone, shale, and limestone do in unaltered formations. Thin seams of pebbly grit with well-rounded water-worn pebbles may be observed running parallel with the folia of a schist, as a seam of fine grit or conglomerate may be seen to do in a series of shales. Nay, even the false-bedding so characteristic of mechanical sediment may be observed among these metamorphic rocks. The metamorphism is not uniform in these regions. Here and there it becomes intensified, and the rocks assume a thoroughly crystalline and much disturbed aspect. But as they recede from these areas they are found to lose much of their foliated character, and indeed to present such slight traces of metamorphism that they can be at once recognized as greywackes, grits, and shales. Moreover, they have been thrown into anticlinal and synclinal folds, and in these and other larger features of geological structure they differ in no essential respect from ordinary unaltered strata. Lastly, fossiliferous limestones containing Silurian shells have been found at their base, so that they have all been formed long after the seas over the area of Britain had been tenanted by living organisms.

Professor Sedgwick and Mr Darwin pointed out many years ago that a crystalline rearrangement of mineral matter has in some cases taken place along the planes of cleavage. We have already observed that the water which has been the great agent of metamorphism must always have followed the dominant divisional planes of a rock. If these planes were those of cleavage, the foliation would doubtless be produced along them, irrespective of the original laminae of deposit. So long as the rock remained tolerably homogeneous in chemical composition, there seems no reason why foliation along the cleavage should differ in any material respect from that along stratification. But it may be doubted whether a cleavage foliation could run without sensible and even very serious interruptions over wide areas. For, in the first place, in most large masses of sedimentary matter we encounter alternations of different kinds of sediment, which could not but produce distinct kinds of rock under the influence of metamorphic change. In the second place, cleavage depends for its perfection and continuity on the fineness of grain of the rock through which it runs. While exceedingly perfect in a mass of argillaceous strata, it becomes ræbber or even dies out in a coarse sandy or gritty rock. Hence, where foliation coincides with cleavage over large tracts, there will almost certainly be bands, more or less distinct, coincident with the original stratification, and running oblique to the general foliation, like bedding and cleavage, save where these two kinds of structure may happen to coalesce.

In a region of intense metamorphism the foliation of the schists may be observed to become here and there somewhat indefinite, until it disappears altogether, and the rocks assume a thoroughly granitic character. Between gneiss and granite there is no difference in mineralogical composition; in the one rock the minerals are arranged in folia, in the other they have no definite arrangement. Gneiss might be called a foliated granite; granite might be termed a non-foliated gneiss. The two rocks may be observed to graduate into each other. In Aberdeenshire, for example, the common grey mica-schist and gneiss may be seen to pass insensibly into the ordinary grey granite. In such cases it has been naturally concluded that granite is the ultimate stage of metamorphism. Judged merely from their composition and microscopic structure, an intrusive

granite connected with igneous protrusions and a metamorphic granite representing the thorough transformation of stratified rock cannot be distinguished from each other.

There is thus nothing improbable in the idea that the same mineral particles may have gone through many successive cycles of change. We may suppose them to have been originally part of a granite mass, and to have been subsequently exposed at the surface by enormous denudation. Worn away from their parent granite they would be washed down with other particles, and spread out under water as parts of sandy or muddy deposits. Buried under a gradual accumulation of sedimentary material thousands of feet in thickness they might be depressed deep beneath the surface, and be thus brought within the influence of metamorphism. Gradually recombined, crystallized, and converted into schistose rock, they might be eventually reduced to the condition of granite, and protruded into some of the overlying less metamorphosed masses in the form of granite veins. Or we may conceive, as already (*ante*, p. 309) suggested, that a communication was opened between the granite thus produced and the surface, and that the original mineral particles, whose vicissitudes we have been tracing, were erupted to the surface as part of a stream of lava.

Possible Metamorphism of Igneous Rocks.—In most large tracts of foliated rocks there occur masses less distinctly foliated or quite granitoid in texture, formed mainly of hornblende or of that mineral in combination with others. Zones or bosses of hornblende-rock and hornblende-schist frequently appear among gneiss and mica-schist. Varieties of quartz-porphyrus occur in a similar way. Bands of fine unctuous chloritic schists may also often be traced. It is not easy to understand how such rocks, at least those containing a large percentage of magnesia, could be produced by the metamorphism of ordinary sediment. The difficulty may perhaps be removed if we regard them as having originally been igneous rocks, either erupted at the surface or intrusively injected among the surrounding rocks previous to metamorphism. Such mineral masses as varieties of syenite and diorite, rich in hornblende or other magnesium silicates, might have been the original condition of many of the rocks here referred to. The fine magnesian schists might be regarded as having been at first tufts associated with the lava-form masses.

Structure of Metamorphic Rocks in the Field.—As the series of metamorphic rocks ranges from scarcely altered sedimentary strata on the one hand to crystalline amorphous granitic masses on the other, they must obviously possess a great range of structure as parts of the architecture of the solid land. In particular they must under different circumstances present the features now of aqueous and now of igneous rocks. The most typical form of metamorphism being foliation, we may consider the structure of foliated rocks as the most characteristic. From what has been said above, it is evident that the planes of foliation give the rocks a general resemblance to stratified sedimentary masses. But these planes are seldom so definite and persistent as those of stratification. They do not impart to the rocks the same tendency to split up into well-marked parallel beds. On the contrary they are often so folded or welded together, especially in the coarse and most crystalline gneisses, that they hardly serve as divisional planes at all, but leave the firm tough rock to split up along other lines.

With care and patience lines of anticlinal and synclinal fold may often be traced among foliated as well as among unaltered rocks. But the unravelling of these and other features of structure is much more difficult than among ordinary stratified formations. This arises partly from the frequent absence of conspicuous and persistent bands which could be used as horizons in working out geological

structure, partly from the abundant crumpling which most foliated rocks have undergone, whereby the continuity of the individual bands is much disturbed or entirely destroyed.

The joints among foliated rocks to which the regular and parallel folia impart a marked fissility resemble those among sedimentary strata. Where, however, the foliation is of a more massive kind, as in the coarser varieties of gneiss, the system of jointing approximates to that of granite or one of the more crystalline igneous rocks.

IX. MINERAL VEINS.

The fissures which so abundantly traverse the crust of the earth have in many instances served as places for the deposit of mineral matter quite distinct from that of the rocks through which they run. As metallic ores frequently occur among the minerals so deposited, and have been extensively worked, a large amount of information has been obtained by mining operations regarding these fissures, or, as they are termed, *mineral veins*. A general though not invariable relation exists between the nature of the minerals in the fissures and that of the contiguous rocks. When the latter are calcareous, calcite usually forms a conspicuous feature in the veins; among siliceous rocks quartz is abundant. These and the other minerals are for the most part well crystallized or at least largely crystalline in the veins, even when the adjoining rocks are granular or amorphous. They are termed *vein-stones*. Since the joints, faults, and fissures which have been filled with new mineral substances are commonly highly inclined or vertical, mineral veins generally run as steep wall-like bands across the rocks in which they occur. Their minerals are arranged in strips, which on the whole run parallel with the walls of the vein (fig. 58).

FIG. 58.—a, Coating of one mineral, say quartz; b, coating of a second mineral, say fluor spar; c, coating of third mineral, or of a third, say sulphate of barytes; d, rib of ore, as copper or lead; e, in walls of the lode.

Mineral veins become *metalliferous*, when among their vein-stones there occur detached crystals or particles, or branching strings and threads, or concretionary masses or parallel bands of native metal, or of the sulphides, oxides, or other ores of metals. The association of these various substances within the two walls or cheeks of a vein is often in a double set of parallel bands, those in one-half of the vein being repeated in the other. The middle of the vein, for example, may consist of galena flanked and partially mixed up with zinc-blende and pyrites. On either side of this central rib there may be a layer of some veinstone, perhaps fluor spar, then a duplicate band of another veinstone, such as barytes or quartz, and so on, to the outer edge of the vein (fig. 58). In other cases, as in auriferous veins of quartz, the vein consists wholly or almost wholly of one vein-stone through which the ore is disseminated in minute grains and strings, so that the vein-stone must be extracted and crushed to obtain the metal by washing.

Mineral veins (*lodes, rake-veins*) vary in thickness from only an inch or less up to many fathoms. Extraordinary variations may be traced even in the course of the same vein, a breadth of several feet or yards rapidly diminishing until the two walls nearly or quite meet, to the exclusion of the minerals of the vein. Similar diversities may be observed in the horizontal extent of veins, some being traceable for miles, others disappearing in a few yards.

They sometimes occupy fissures without any throw, but most frequently seem to occur along lines of fault. In some cases indeed it can be shown that dislocation has taken place after some portion of the vein had been formed, but before the completion of the process. They usually send out branches, and in some mining districts do this to such an extent that it becomes hardly possible to identify the main vein among its numerous offshoots.

The direction of the veins varies in different districts. Two series may often be traced,—a principal series running in one general direction, and a minor set crossing the first at right angles or obliquely. Great differences in the richness of a metallic lode may be observed as it is worked vertically and horizontally, some of these depending in a way not easily explained upon the nature of the surrounding rock. Among the Cornish lodes, for example, some contain copper only where they traverse the Devonian slates, and lose it where they enter the granite, where tin takes its place. In the lead tracts of the north of England the metal diminishes where the veins lie in shale, and augments where they run through limestone.

In some rocks, more especially in limestones, large subterranean cavities have been filled with vein-stones and ores. The iron mines of the English lake district, for example, lie in the Carboniferous Limestone, where tunnels and caverns anciently dissolved out of the rock by percolating or running water have been subsequently filled up with hematite. In the lead districts of the north of England also, similar cavities have received a plentiful deposit of vein-stones and galena with its accompanying ores.

Various theories have been proposed to account for the infilling of mineral veins. Of these the most noteworthy are—(1) the theory of lateral segregation,—which teaches that the substances in the veins have been derived from the adjacent rocks by a process of solution and redeposit; and (2) the theory of infilling from below,—according to which the minerals and ores were introduced from below dissolved in water or steam, or by sublimation, or by igneous fusion and injection.

The fact that the nature and amount of the minerals, and especially of the ores, in a vein vary with the nature of the surrounding rocks seems to show that these rocks have had a certain influence on the precipitation of mineral matter in the fissures passing through them. But that this mineral matter came chiefly from below appears almost certain. The phenomena of the ascent of hot water in volcanic districts afford a close analogy to what has occurred in mineral veins. It is known that at the present time various minerals, including silica, both crystalline and alcedonic, and various metallic sulphides, are being deposited in fissures up which hot water rises. At the same time it is conceivable that to some extent there may be a decomposition of the rocks on either side of a fissure, and that a portion of the mineral matter abstracted may be laid down in another form along the walls of the fissure, or, on the other hand, that the rocks on either side of the fissure may be permeated for some distance by the ascending waters, and that some of the mineral substances carried up in solution may be deposited in the pores and cavities of these rocks as well as in the fissure itself.

X. UNCONFORMABILITY.

Where one series of rocks, whether of aqueous or igneous origin, has been laid down continuously and without disturbance upon another series, they are said to be *conformable*. Thus in fig. 59 the sheets of rock numbered 1, 2, 3,

FIG. 59.—Overlap of conformable strata.

and 4 have succeeded each other in regular order, and exhibit a perfect conformability. They overlap each other, however, No. 2 extending beyond the edge of No. 1, No. 3 beyond that of No. 2, and so on. As already explained (p. 295), this structure points to a gradual subsidence and enlargement of the area of deposit. But all these conformable beds repose against the older platform A, with which they have no direct connexion. That platform may consist of horizontal or inclined strata, or contorted schist, or crystalline igneous rocks. In any case there is a complete break between it and the overlying rocks, which rest successively on different parts of the older mass. This relation is termed an *unconformability*. The upper conformable beds in fig. 59 are said to lie unconformably upon A.

It is evident that this structure may occur in ordinary stratified, or in igneous, or in metamorphic rocks, or between any two of these great series. It is most familiarly displayed among stratified masses, and can there be most satisfactorily studied. The lines of bedding furnish a ready means of detecting differences of inclination and discordances of superposition. But even among igneous protrusions and in ancient metamorphic masses, distinct evidence of unconformability is not always difficult to trace.

Though conformable rocks may usually be presumed to have followed each other continuously without any great disturbance of geographical conditions, we cannot always be sure in such an inference. But an unconformability leaves no room to doubt that it marks a decided break in the continuity of deposit. Hence no kind of geological structure is of higher importance in the interpretation of the history of the stratified formations of a country. In rare cases an unconformability may occur between two horizontal groups of strata. In fig. 60, for instance, a set of beds C is shown

FIG. 60.—Unconformability among horizontal beds.

to lie conformably for some distance upon an older series A. Were nothing more to be seen than what appears towards the right hand, we might justifiably conclude the whole of the rocks to be conformable. By passing to the left, however, we should find evidence of the older group having been upraised and unequally denuded before the deposition of the newer. The denudation would show that the conformability was accidental, that the older rocks had really been upraised and worn down before the formation of the newer. In such a case the upheaval must have been so equal as not to disturb the horizontality of the lower rocks.

As a rule, however, it seldom happens that movements of this kind have taken place over an extensive area so

equally as not to produce a want of conformability somewhere between the older and newer rocks. Most frequently the older formations have been disturbed, tilted at various angles, or even placed on end. They have likewise been irregularly and enormously worn down. Hence, instead of lying parallel, the younger beds run transversely across the upturned denuded ends of the older. The greater the

FIG. 61.—Section of unconformable rocks.

disturbance of the older rocks the more marked is the unconformability. In fig. 61, for instance, the series of beds A is unconformably covered by the series C. At both sides of the arch the unconformability is strongly marked, but at the centre d the two series seem to be conformable. An unconformability forms one of the great breaks in the geological record. In the foregoing figure, by way of illustration, we see at once that a notable hiatus in deposition, and therefore in geological chronology, must exist between series A and C. The older rocks had been deposited, folded, upheaved, and worn down before the accumulation of the newer series upon their denuded edges. These changes must have demanded a considerable lapse of time. Yet, looking merely at the structure in itself, we have evidently no means of fixing, even relatively, the length of interval marked by an unconformability. The mere violence of contrast between a set of vertical beds below and a horizontal group above it is no reliable criterion of the relative lapses of time between their deposition, for an older portion of a given formation might be tilted on end and be overlaid unconformably by a later part of the same formation. A set of flat rocks of high geological antiquity might, on the other hand, be covered by a formation of comparatively recent date, yet in spite of the want of discordance between the two, they might have been separated by a large portion of the total sum of geological time. It is by the evidence of organic remains that the relative importance of unconformabilities must be measured, as will be explained in part v.

Paramount though the effect of an unconformability may be in the geological structure of a country, it must nevertheless be in almost all cases local. The disturbance by which it was produced can have effected but a comparatively circumscribed region, beyond the limits of which the continuity of sedimentation may have been undisturbed. We may therefore always expect to be able to fill up the gaps in one district from the more complete geological formations of another. In fig. 61 we see that something is wanting between A and C. But in the structure of another country or a different part of the same country we might discover

FIG. 62.—Section showing the groups of fig. 61 in conformable sequences, with the intervening blank (B) supplied.

the complete succession, as in fig. 62, where the whole of the rocks succeed each other conformably, and where the gap between A and C marked by the unconformability in fig. 61 is bridged over by the intermediate group of strata B.

PART V.—PALÆONTOLOGICAL GEOLOGY.

Palæontology is the science which treats of the structure, affinities, classification, and distribution in time of the forms of plant and animal life embedded in the rocks of the earth's crust. In one sense it may be regarded as a branch of zoology and of botany, its claim in this view to rank as a separate science resting almost solely on the fact that of the forms with which it deals but a small proportion belongs to the living world. In another aspect it may be looked upon as a branch of geology, seeing that its assistance is absolutely indispensable in many of the most familiar and fundamental problems of the latter science. It is under this last aspect that we have to regard it here. We shall consider merely those leading features of palæontological inquiry without some knowledge of which progress in modern geology would be impossible.

Fossils.—Palæontological geology, then, deals with the fossils or organic remains preserved in the rocks, and endeavours to gather from them information as to the history of the globe and its inhabitants. The term "fossil," meaning literally anything "dug up," was formerly applied indiscriminately to any mineral substance taken out of the earth's crust, whether organized or not. Ordinary minerals and rocks were thus included as fossils. For many years, however, the meaning of the word has been restricted, so as to include only the remains or traces of plants and animals preserved in any natural formation whether hard rock or superficial deposit. The idea of antiquity or relative date is not necessarily involved in this conception of the term. Thus the bones of a sheep buried under gravel and silt by a modern flood, and the obscure crystalline traces of a coral in ancient masses of limestone, are equally fossils.

Nor has the term fossil any limitation as to organic grade. It includes not merely the remains of organisms, but also whatever was directly connected with or produced by these organisms. Thus the resin which was exuded from trees of long-preserved forests is as much a fossil as any portion of the stem, leaves, flowers, or fruit, and in some respects is even more valuable to the geologist than more determinable remains of its parent trees, because it has often preserved in admirable perfection the insects which fitted about in the woodlands. The burrows and trails of a worm preserved in sandstone and shale claim recognition as fossils, and indeed are commonly the only indications to be met with of the existence of annelid life among old geological formations. The droppings of fishes and reptiles, called coprolites, are excellent fossils, and tell their tale as to the presence of vertebrate life in ancient waters. The little agglutinated cases of the caddis-worm remain as fossils in formations from which perchance most other traces of life may have passed away. Nay, the very handiwork of man, when preserved in any natural manner, is entitled to rank among fossils; as where his flint-instruments have been dropped into the prehistoric gravels of river-valleys, or where his canoes have been buried in the silt of lake-bottoms.

The term fossil, moreover, suffers no restriction as to the condition or state of preservation of any organism. In some rare instances the very flesh, skin, and hair of a mammal have been preserved for thousands of years, as in the case of the mammoths entombed within the frozen mud cliffs of Siberia. In most cases all or most of the original animal matter has disappeared, and the organism has been more or less completely mineralized or petrified. It often happens that the whole organism has decayed, and a mere cast in amorphous mineral matter, as sand, clay, ironstone, silica, or limestone remains, yet all these variations must be comprised in the comprehensive term fossil.

Conditions for the Preservation of Organic Remains.—At the outset the question naturally suggests itself how the

remains of plants and animals come to have been preserved in rocks at all. If we observe what takes place at the present day, and argue that it may fairly be taken as an indication of what has been the ordinary condition of things in the geological past, we see that there must have been so many chances against the conservation of either animal or plant remains that their occurrence among stratified formations should be regarded as exceptional, and as the result of various fortunate accidents.

I. Consider, in the first place, what chances exist for the preservation of remains of the present fauna and flora of a country. The surface of the land may be densely clothed with forest, and abundantly peopled with animal life. But the trees die and moulder into soil. The animals, too, disappear, generation after generation, and leave no perceptible traces of their existence. If we were not aware from authentic records that central and northern Europe was covered with vast forests at the beginning of our era, how could we know this fact? What has become of the herds of wild oxen, the bears, wolves, and other denizens of primeval Europe? How could we prove from the examination of the surface soil of any country that those creatures had once abounded there? We might search in vain for any such superficial traces, and would learn by so doing that the law of nature is everywhere "dust to dust."

The conditions for the preservation of any relics of the plant and animal life of a terrestrial surface must therefore be always exceptional. They are supplied only where the organic remains can be protected from the air and superficial decay. Hence they may be observed in

1. *Lakes.*—Over the floor of a lake deposits of silt, peat, marl, &c., are formed. Into these the stems, branches, leaves, flowers, fruits, or seeds of plants from the neighbouring land may be carried, together with the bodies of land animals, insects, and birds. An occasional storm may blow the lighter debris of the woodlands into the water. Such portions of the wreck as did not float, and were not washed ashore again, might sink to the bottom. Of these the larger part would in most cases probably rot away, so that, in the end, only a very small fraction of the whole vegetable matter cast over the lake by the wind would be covered up and preserved at the bottom. In like manner the animal remains swept by winds or by river floods into the lake would run so many risks of dissolution that only a proportion of them, and probably merely a small proportion, would be preserved. When we consider these chances against the conservation of the vegetable and animal life of the land, we must admit that, at the best, lake-bottoms can contain but a meagre and imperfect representation of the abundant life of the adjacent hills and plains.

But lakes have a distinct flora and fauna of their own. Their aquatic plants may be entombed in the gathering deposits of the bottom. Their mollusks, of characteristic types, sometimes form, by the accumulation of their remains, sheets of soft calcareous marl, in which many of the undecayed shells are preserved. Their fishes, likewise distinctly lacustrine, no doubt must often be entombed in the silt or marl.

2. *Peat-mosses.*—Wild animals venturing on the more treacherous watery parts of a peat-bog are sometimes engulfed or "laired." The antiseptic qualities of the peat preserve such remains from decay. Hence from European peat-mosses numerous remains of deer and oxen have been exhumed. Evidently the larger beasts of the forest ought chiefly to be looked for in these localities.

3. *Deltas at River Mouths.*—From what has been said in previous pages (*ante*, pp. 276-8) regarding the geological operations of rivers, it is obvious that to some extent both the flora and the fauna of the land may be buried among the sand and silt of deltas. When we consider, however, that though occasional or frequent river-floods sweep down

trees, herbage, and the bodies of land animals, the remains so transported run every risk of decaying or being otherwise destroyed while still afloat, and that even if they reach the bottom they will tend to dissolution there unless speedily covered up and protected by fresh sediment, we must perceive that delta formations can scarcely be expected to give us more than a meagre outline of the varied terrestrial flora and fauna.

4. *Caverns*.—These are eminently adapted for the preservation of the higher forms of terrestrial life. Most of our knowledge of the prehistoric mammalian fauna of Europe is derived from what has been disinterred from *bone-caves*. As these recesses lie for the most part in limestone or in calcareous rock, their floors are commonly coated with stalagmite from the drip of the roof; and as this deposit is of great closeness and durability it has effectually preserved whatever it has covered or enveloped. The caves have in many instances served predatory beasts, like the hyæna, cave-lion, and cave-bear, as dens in which they slept, and into which some of them dragged their prey. In other cases they have been merely holes into which different animals crawled to die, or into which they fell or were swept by inundations. Under whatever circumstances the animals left their remains in these subterranean retreats, the result has been that the bones have been covered up and preserved. Still, we must admit that after all but a mere fraction even of the mammals of the time would enter the caves, and therefore that the evidence of the cavern-deposits, profoundly interesting and valuable as it is, presents us with merely a glimpse of one aspect of the life of the land.

II. In the next place, if we turn to the sea, we find certainly many more favourable conditions for the preservation of organic forms, but also many circumstances which operate against it. While the level of the land remains stationary, there can be but little effective entombment of marine organisms in littoral deposits; for only a limited accumulation of sediment will be formed until subsidence of the sea-floor takes place. In the trifling beds of sand or gravel thrown up on a stationary shore, only the harder and more durable forms of life, such as gasteropods and lamellibranchs, which can withstand the tritulating effects of the beach waves, are likely to remain uneffaced.

Below tide-marks, along the margin of the land where sediment is gradually deposited, the conditions are favourable for the preservation of marine organisms. Sheets of sand and mud are there laid down. In those sediments the harder parts of many forms of life may be entombed and protected from decay. But only a small proportion of the total marine fauna may be expected to occur in such deposits. At the best, merely littoral and shallow-water forms will occur, and even under the most favourable conditions they will represent but a fraction of the whole assemblage of life in these juxta-terrestrial parts of the ocean. As we recede from the land the rate of deposition of sediment on the sea-floor must become feebler, until in the remote central abysses it reaches a hardly appreciable minimum. Except, therefore, where organic deposits, such as ooze, are forming in these more pelagic regions, the conditions must be on the whole unfavourable for the preservation of any adequate representation of the deep-sea fauna. Hard enduring objects, such as teeth and bones, may slowly accumulate and be protected by a coating of peroxide of manganese, or of some of the silicates above (p. 288) referred to as now forming here and there over the deep-sea-bottom. But such a deposit, if raised into land, would supply but a meagre picture of the life of the sea.

We must conclude therefore that of the whole sea-floor the area best adapted for preserving a varied suite of marine organic exuvie is that belt which, running along

the margin of the land, is ever receiving fresh layers of sediment transported by rivers and currents from the adjacent shores. The most favourable conditions for the accumulation of a thick mass of marine fossiliferous strata will arise when the area of deposit is undergoing a gradual subsidence. If the rate of depression and that of deposit were equal, or nearly so, the movement might proceed for a vast period without producing any great apparent change in marine geography, and even without seriously affecting the distribution of life over the sea-floor within the area of subsidence. Hundreds or thousands of feet of sedimentary strata might in this way be heaped up round the continents, containing a fragmentary series of organic remains belonging to those forms of shallow-water life which had hard parts capable of preservation.

There can be little doubt that such has in fact been the history of the lazan mass of stratified formations in the earth's crust. These piles of marine strata have unquestionably been laid down in comparatively shallow water within the area of deposit of terrestrial sediment. Their great depth seems only explicable by prolonged and repeated movements of subsidence, interrupted, however, as we know, by other movements of a contrary kind. These geographical changes affected at once the deposition of inorganic materials and the succession of organic forms. One series of strata is sometimes abruptly succeeded by another of a very different character, and we generally find a corresponding contrast between their respective organic contents.

It follows from these conclusions that representatives of the abyssal deposits of the central oceans are not likely to be met with among the geological formations of past times. Thanks to the great work done by the "Challenger" expedition, we now know what are the leading characters of these abyssal deposits of the present day. They have absolutely no analogy among the formations of the earth's crust. They differ, indeed, so entirely from any formation which geologists considered to be of deep-water origin as to indicate that, from early geological times, the present great areas of land and sea have remained on the whole where they are, and that the land consists mainly of strata formed at successive epochs of terrestrial debris laid down in the surrounding shallow sea.

Relative Value of Organic Remains as Fossils.—As the conditions for the preservation of organic remains exist more favourably under the sea than on land, marine organisms must be far more abundantly conserved than those of the land. This is true to-day, and has been true in all past geological time. Hence for the purposes of the geologist the fossil remains of marine forms of life far surpass all others in value. Among them there will necessarily be a gradation of importance regulated chiefly by their relative abundance. Now, of all the marine tribes which live within the juxta-terrestrial belt of sedimentation, unquestionably the *Mollusca* stand in the place of pre-eminence as regards their aptitude for becoming fossils. In the first place they almost all possess a hard durable shell, capable of resisting considerable abrasion, and readily passing into a mineralized condition. In the next place they are extremely abundant both as to individuals and genera. They occur on the shore within tide mark, and range thence down into the abysses. Moreover, they appear to have possessed those qualifications from early geological times. In the marine *Mollusca*, therefore, we have a common ground of comparison between the stratified formations of different periods. They have been styled the alphabet of palæontological inquiry. It will be seen, as we proceed, how much in the interpretation of geological history depends upon the testimony of sea-shells.

Looking at the organisms of the land, we perceive that, as a rule, the abundant terrestrial flora has a comparatively

small chance of being well represented in a fossil state, that indeed, as a rule, only that portion of it of which the leaves, twigs, flowers, and fruits are blown into lakes is likely to be partially preserved. Terrestrial plants, therefore, occur in comparative rarity among stratified rocks, and furnish in consequence only limited means of comparison between the formations of different ages and countries. Of land animals the vast majority perish and leave no permanent trace of their existence. Predatory and other forms whose remains may be looked for in caverns or peat-mosses, must occur more numerously in the fossil state than birds, and are correspondingly more valuable to the geologist for the comparison of different strata.

Relative Age of Fossils.—Although absolute dates cannot be fixed in geological chronology, it is not difficult to determine the relative age of different strata, and consequently of their enclosed organic remains. For this purpose the fundamental law is based on what is termed the "order of superposition." This law may be thus defined,—in a series of stratified formations the older must underlie the younger. It is not needful that we should actually see the one lying below the other. If a continuous conformable succession of strata dips steadily in one direction we know that the beds at the one end must underlie those at the other, because we can trace the whole succession of beds between them. Rare instances occur where strata have been so folded by great terrestrial disturbance that the younger are made to underlie the older. But this inversion can usually be made quite clear from other evidence. The true order of superposition is decisive of the relative ages of stratified rocks.

If therefore formations lie regularly above each other, B upon A, C upon B, D upon C, and so on, it is evident that the organic remains found in A must have lived and died before those in B were entombed, the latter must have been covered up before those in C, and these again before those in D. The chronological sequence of fossils must be determined first of all by the order of superposition of their enclosing strata. There is nothing in the fossils themselves, apart from experience, to fix their date. Unless, for example, we knew from observation or testimony that *Rhynchonella pleurodon* is a shell of the Carboniferous Limestone, and *Rhynchonella tetrahedra* is a shell of the Liass, we could not, from mere inspection of the fossils themselves, pronounce as to their real geological position. It is quite true that by practice a palæontologist has his eye so trained that he can make shrewd approximations to the actual horizon of fossils which he may never have seen before, but he can only do this by availing himself of a wide experience based upon the ascertained order of appearance of fossils as determined by the law of superposition. For geological purposes therefore, and indeed for all purposes of comparison between the faunas and floras of different periods, it is absolutely essential first of all to have the order of superposition of strata rigorously determined. Unless this is done the most fatal mistakes may be made in palæontological chronology. But when it has once been done in one typical district, the order thus established may be held as proved for a wide region where, from paucity of sections, or from geological disturbance, the true succession of formations cannot be satisfactorily determined.

Uses of Fossils in Geology.—There are two main purposes to which fossils may be put in geological research—(1) to throw light upon former conditions of physical geography, such as the presence of land, rivers, lakes, and seas, in places where they do not now exist, changes of climate, and the former distribution of plants and animals; and (2) to furnish a guide in geological chronology whereby rocks may be classified according to relative date, and the facts of geological history may be arranged and interpreted as a connected record of the earth's progress.

1 A few examples will suffice to show the manifold assistance which fossils furnish to the geologist in the elucidation of ancient geography.

(a) Former land-surfaces are revealed by the presence of tree-stumps in their positions of growth, with their roots branching freely in the underlying stratum, which, representing the ancient soil, often contains leaves, fruits, and other sylvan remains, together with traces of the bones of land animals, remains of insects, land-shells, &c. Ancient woodland surfaces of this kind are found between tide-marks, and even below low-water line, round different parts of the British coast. They unequivocally prove a subsidence of the land. Of more ancient date are the "dirt-beds" of Portland, which, by their layers of soil and tree-stumps, show that woodlands of cyads sprang up over an upraised sea-bottom and were buried beneath the silt of a river or lake. Still further back in geological history come the numerous coal-growths of the Carboniferous period, pointing to wide jungles of terrestrial or aquatic plants, like the modern mangrove swamps, which were submerged and covered with sand and silt.

(b) The former existence of lakes can be satisfactorily proved from beds of marl or lacustrine limestone full of fresh-water shells, or from fine silt with leaves, fruits, and insect remains. Such deposits are abundantly forming at the present day, and they occur at various horizons among the geological formations of past times. The well-known nagelfluë of Switzerland—a mass of conglomerate attaining a thickness of fully 6000 feet—can be shown from its fossil contents to be essentially a lacustrine formation.

(c) Old sea-bottoms are vividly brought before us by beds of marine shells and other organisms. Layers of water-worn gravel and sand, with rolled shells of littoral and infra-littoral species, unmistakably mark the position of a former shore line. Deeper water is indicated by finer muddy sediment, with relics of the fauna which prevails beneath the reach of waves and ground-swell. Limestones full of corals, or made up of crinoids, point to the slow continuous growth and decay of generation after generation of organisms in clear sea-water.

(d) Variations in the nature of the water or of the sea-bottom may sometimes be shown by changes in the size or shape of the organic remains. If, for example, the fossils in the central and lower parts of a limestone are large and well-formed, but in the upper layers become dwarfed and distorted, we may reasonably infer that the conditions for their continued existence at that locality must have been gradually impaired. The final complete cessation of these favourable conditions is shown by the replacement of the limestone by shale, indicative of the water having become muddy, and by the disappearance of the fossils, which had shown their sensitiveness to the change.

(e) That the sea-floor represented by a fossiliferous stratum was not far from land is sufficiently proved by mere lithological characters, as has been already explained; but the conclusion may be further strengthened by the occurrence of leaves, stems, and other fragments of terrestrial vegetation which, if found in some numbers among marine organisms, would make it improbable that they had been drifted far from land.

(f) The existence of different conditions of climate in former geological periods is satisfactorily demonstrated from the testimony of fossils. Thus an assemblage of the remains of palms, gourds, and melons, with bones of crocodiles, turtles, and sea-snakes, proves a sub-tropical climate to have prevailed over the south of England in the time of the older Tertiary formations. On the other hand, the presence of an intensely cold or arctic climate far south in Europe during post-Tertiary time can be shown, from different kinds of evidence, such as the existence of the remains of arctic animals even as far as the south of England and of France.

This is a use of fossils, however, where great caution must be used. We cannot affirm that, because a certain species of a genus lives now in a vain part of the globe, every species of that genus must always have lived in similar circumstances. The well-known example of the mammoth and woolly rhinoceros having lived in the cold north, while their modern representatives inhabit some of the warmest regions of the globe, may be usefully remembered as a warning against any such conclusions. When, however, we find that not one fossil merely, but the whole assemblage of fossils in a formation has its modern analogue in a certain general condition of climate, we may at least tentatively infer that the same kind of climate prevailed where that assemblage of fossils lived. Such an inference would become more and more unsafe in proportion to the antiquity of the fossils and their divergence from existing forms.

2. When the order of superposition has been determined in a great series of stratified formations, it is found that the fossils at the bottom are not quite the same as those at the top of the series. As we trace the beds upward we discover that species after species of the lowest platforms disappears, until perhaps not one of them is found. With the cessation of these older species others make their entrance. These in turn are found to die out and to be replaced by newer forms. After patient examination of the rocks, it is ascertained that every well-marked formation is characterized by its own species or genera, or by a general assemblage or *faunes* of organic forms. This can only, of course, be determined by actual practical experience over an area of some size. When the typical fossils of a formation are known, they serve to identify that formation in its progress across a country. Thus, as we trace the formation into tracts where it would be impossible to determine the true order of superposition, owing to the want of sections, or to the disturbed condition of the rocks, we can employ the fossils as a means of identification, and speak with confidence as to the succession of the rocks. We may even demonstrate that in some mountainous ground the beds have been turned completely upside down, if we can show that the fossils in what are now the uppermost strata ought properly to lie underneath those in the beds below them.

Observations made over a large part of the surface of the globe have enabled geologists to divide the stratified part of the earth's crust into systems, formations, and groups or series. These subdivisions are frequently marked off from each other by lithological characters. But mere lithological differences would afford at the best but a limited and local ground of separation. Two masses of sandstone, for example, having exactly the same general external and internal characters, might belong to very different geological periods. On the other hand, a series of limestones in one locality might be the exact chronological equivalent of a set of sandstones and conglomerates at another, and of a series of shales and clays at a third.

It is by their characteristic fossils that the divisions of the stratified rocks can be most satisfactorily made. Each formation being distinguished by its own assemblage of organic remains, it can be followed and recognized even amid the crumplings and dislocations of a disturbed region. The same general succession of organic types can be observed over a large part of the world, though, of course, with important modifications in different countries. This similarity of succession has been termed *homotaxis*—a term which expresses the fact that the order in which the leading types of organized existence have appeared upon the earth has been similar even in widely separated regions.

It is evident that in this way a method of comparison is furnished whereby the stratified formations of different parts of the earth's crust can be brought into relation with each other. We find, for example, that a certain series of strata

is characterized in Britain by certain genera and species of corals, brachiopods, lamellibranchs, gasteropods, and cephalopods. A group of rocks in Bohemia, differing more or less from these in lithological aspect, contains on the whole the same genera, and many even of the same species. In Scandinavia a set of beds may be seen unlike, perhaps, in external characters to the British type, but yielding many of the same fossils. In Canada and many parts of the northern United States, other rocks enclose many of the same, and of closely allied genera and species. All these groups of strata are classed together as *homotaxial*, that is, as having been deposited during the same relative period in the general progress of life in each region.

It was at one time believed, and the belief is still far from extinct, that groups of strata characterized by this community or resemblance of organic remains were chronologically contemporaneous. But such an inference rests upon most insecure grounds. We may not be able to disprove the assertion that the strata were strictly coeval, but we have only to reflect on the present conditions of zoological and botanical distribution, and of modern sedimentation, to be assured that the assertion of contemporaneity is a mere assumption. Consider for a moment what would happen were the present surface of any portion of central or southern Europe to be submerged beneath the sea, covered by marine deposits, and then re-elevated into land. The river-terraces and lacustrine mounds formed before the time of Julius Cesar could not be distinguished by any fossil tests from those laid down in the days of Victoria, unless, indeed, traces of human implements were obtainable whereby the progress of civilization during 2000 years might be indicated. So far as regards the shells, bones, and plants preserved in the various formations, it would be absolutely impossible to discriminate their relative dates; they would be classed as "geologically contemporaneous," that is, as having been formed during the same period in the history of life in the European area, yet there might be a difference of 2000 years or more between many of them. Strict contemporaneity cannot be asserted of any strata merely on the ground of similarity or identity in fossils.

But the phrase "geologically contemporaneous" is too vague to have any chronological value except in a relative sense. To speak of two formations as in any sense contemporaneous which may have been separated by thousands of years seems rather a misuse of language, though the phraseology has now gained such a footing in geological literature as probably to be inexpugnable. If we turn again for suggestions to the existing distribution of life on the earth we learn that similarity or identity of species and genera holds good on the whole only for limited areas, and consequently, if applied to wide geographical regions, ought to be an argument for diversity rather than for similarity of age. If we suppose the British seas to be raised into dry land, so that the organic relics preserved in their sands and silts could be exhumed and examined, a general common facies or type would be found, though some species would be more abundant in or entirely confined to the north, while others would show a greater development in the opposite quarter. Still there would be such a similarity throughout the whole that no naturalist would hesitate to regard the organisms as those of one biological province, and belonging to the same great geological period. The region is so small, and its conditions of life so uniform and uninterrupted, that no marked distinction is possible between the forms of life in its different parts.

Widening the area of observation, we perceive that as we recede from any given point the forms of life gradually change. Vegetation alters its aspect from climate to climate, and with it come corresponding transformations in the character of insects, birds, and wild animals. A lake bottom

would preserve one suite of organisms in England, but a very different group at the foot of the Himalaya Mountains, yet the deposits at the two places might be absolutely coeval, even as to months and days. Hence it becomes apparent that while strict contemporaneity cannot be predicated of deposits containing the same organic remains, it may actually be true of deposits in which they are quite distinct.

If, then, at the present time, community of organic forms obtains only in districts, regions, or provinces, it may have been more or less limited also in past time. Similarity or identity of fossils among formations geographically far apart, instead of proving contemporaneity, ought rather to be looked upon as indicative of great discrepancies in the relative epochs of deposit. For in any theory of the origin of species, the spread of any one species, still more of any group of species to a vast distance from the original centre of dispersion, must in most cases have been inconceivably slow. It must have occupied so prolonged a time as to allow of almost indefinite changes in physical geography. A species may have disappeared from its primeval birthplace while it continued to flourish in one or more directions in its outward circle of advance. The date of the first appearance and final extinction of that species would thus differ widely according to the locality at which we might examine its remains.

The grand march of life, in its progress from lower to higher forms, has unquestionably been broadly alike in all quarters of the globe. But nothing seems more certain than that its rate of advance has not everywhere been the same. It has moved unequally over the same region. A certain stage of progress may have been reached in one quarter of the globe thousands of years before it was reached in another; though the same general succession of organic forms might be found in each region.

The geological formations form the records of these ages of organic development. In every country where they are fully displayed, and where they have been properly examined, they can be separated out from each other according to their organic contents. Their relative age within a limited geographical area can be demonstrated by the mere law of superposition. When, however, the formations of distant countries are compared, all that we can safely affirm regarding them is that those containing the same or a representative assemblage of organic remains belong to the same epoch in the history of biological progress in each area. They are *homotaxial*; but we cannot assert that they are contemporaneous, unless we are prepared to include within that term a vague period of perhaps thousands of years.

Doctrine of Colonies.—M. Barrande, the distinguished author of the *Système Silurien de la Bohême*, drew attention more than a quarter of a century ago to certain remarkable intercalations of fossils in the series of Silurian strata of Bohemia. He showed that, while these strata presented a normal succession of organic remains, there were nevertheless exceptional bands, which, containing the fossils of a higher zone, were yet included on different horizons among inferior portions of the series. He termed these precursory bands "colonies," and defined the phenomena as consisting in the partial co-existence of two general faunas, which, considered as a whole, were nevertheless successive. He supposed that during the later stages of his second Silurian fauna in Bohemia the first phases of the third fauna had already appeared, and attained some degree of development in some neighbouring but yet unknown region. At intervals, corresponding doubtless to geographical changes, such as movements of subsidence or elevation, volcanic eruptions, &c., communication was opened between that outer region and the basin of Bohemia. During these intervals a greater or less number of immigrants succeeded in making their way into the Bohemian area, but as the conditions for their

prolonged continuance there were not yet favourable, they soon died out, and the normal fauna of the region resumed its occupancy. The deposits formed during these partial interruptions, notably graptolitic schists, accompanied by igneous sheets, contain, besides the invading species, remains of some of the indigenous forms. Eventually, however, on the final extinction of the second fauna, and, we may suppose, on the ultimate demolition of the physical barriers hitherto only occasionally and temporarily broken, the third fauna, which had already sent successive colonies into the Bohemian area, now swarmed into it, and peopled it till the close of the Silurian period.

This original and ingenious doctrine has met with much opposition on the part of geologists and paleontologists. Of the facts cited by M. Barrande there has been no question, but other explanations have been suggested for them. It has been said, for example, that the so-called colonies are merely bands of the Upper Silurian rocks or third fauna, which by great plications have been so folded with the older rocks as to seem regularly interstratified with them. But the author of the *Système Silurien* very justly contends that of such foldings there is no evidence, but that, on the contrary, the sequence of the strata appears normal and undisturbed. Again it has been urged that the difference of organic contents in these so-called colonies is due merely to a difference in the conditions of water and sea bottom, particular species appearing with the conditions favourable to their spread, and disappearing when these ceased. But this contention is really included in M. Barrande's theory. The species which disappear and reappear in later stages must have existed in the meanwhile outside of the area of deposit, which is precisely what he has sought to establish. Much of the opposition which his views have encountered has probably arisen from the feeling that if they are admitted they must weaken the value of paleontological evidence in defining geological horizons. A paleontologist, who has been accustomed to deal with certain fossils as unfailing indications of particular portions of the geological series, is naturally unwilling to see his generalizations upset by an attempt to show that the fossils may occur on a far earlier horizon.

If, however, we view this question from the broad natural history platform from which it was regarded by M. Barrande, it is impossible not to admit that such phenomena as he has sought to establish in Bohemia must have constantly occurred in all geological periods and in all parts of the world. No one now believes in the sudden extinction and creation of entire faunas. Every great fauna in the earth's history must have gradually grown out of some pre-existing one, and must have insensibly graduated into that which succeeded. The occurrence of two very distinct faunas in two closely consecutive series of strata does not prove that the one abruptly died out and the other suddenly appeared in its place. It only shows, as Darwin has so well enforced, the imperfection of the geological record. In the interval between the formation of two such contrasted groups of rocks the fauna of the lower strata must have continued to exist elsewhere, and gradually to change into the newer facies which appeared when sedimentation recommenced with the upper strata. Distinct zoological provinces have no doubt been separated by narrow barriers in former geological periods, as they still are to-day. There seems, therefore, every probability that such migrations as M. Barrande has supposed in the case of the Silurian fauna of Bohemia have again and again taken place. Two notable examples will be given in later pages, one in the Lower and one in the Upper Old Red Sandstone of Scotland.

Gaps in the Geological Record.—The history of life has been very imperfectly preserved in the stratified parts of the earth's crust. Apart from the fact that, even under the

most favourable conditions, only a small proportion of the total flora and fauna of any period could be preserved in the fossil state, enormous gaps occur where no record has been preserved at all. It is as if whole chapters and books were missing from an historical work. Some of these lacunae are sufficiently obvious. Thus, in some cases, powerful dislocations have thrown considerable portions of the rocks out of sight. Sometimes extensive metamorphism has so affected them that their original characters, including their organic contents, have been destroyed. Oftenest of all, denudation has come into play, and vast masses of fossiliferous rock have been entirely worn away. That this cause has operated frequently is shown by the abundant unconformabilities in the structure of the earth's crust.

While the mere fact that one series of rocks lies unconformably on another proves the lapse of a considerable interval between their respective dates, the relative length of this interval may sometimes be demonstrated by means of fossil evidence and by this alone. Let us suppose, for example, that a certain group of formations has been disturbed, upraised, denuded, and covered unconformably by a second group. In lithological characters the two may closely resemble each other, and there may be nothing to show that the gap represented by their unconformability is not of a trifling character. In many cases, indeed, it would be quite impossible to pronounce any well-grounded judgment as to the amount of interval, even measured by the vague relative standards of geological chronology. But if each group contains a well-preserved suite of organic remains, it may not only be possible, but easy, to say exactly how much of the geological record has been left out between the two sets of formations. By comparing the fossils with those obtained from regions where the geological record is more complete, it may be ascertained perhaps that the lower rocks belong to a certain platform or stage in geological history which for our present purpose we may call D, and that the upper rocks can in like manner be paralleled with stage H. It would be then apparent that at this locality the chronicles of three great geological periods E, F, and G were wanting, which are elsewhere found to be intercalated between D and H. The lapse of time represented by this unconformability would thus be equivalent to that required for the accumulation of the three missing formations in those regions where sedimentation went on undisturbed.

But fossil evidence may be made to prove the existence of gaps which are not otherwise apparent. As has been already remarked, changes in organic forms must, on the whole, have been extremely slow in the geological past. The whole species of a sea floor could not pass entirely away, and be replaced by other forms, without the lapse of long periods of time. If then among the conformable stratified formations of former ages we encounter sudden and abrupt changes in the facies of the fossils, we may be certain that these must mark omissions in the record, which we may hope to fill in from a more perfect series elsewhere. The complete contrasts between unconformable strata are sufficiently explicable. It is not so easy to give a satisfactory account of those which occur where the beds are strictly conformable, and where no evidence can be observed of any considerable change of physical conditions at the time of deposit. A group of strata having the same general lithological characters throughout may be marked by a great discrepancy between the fossils above and below a certain line. A few species may pass from the one into the other, or perhaps every species may be different. In cases of this kind, when proved to be not merely local but persistent over wide areas, we must admit, notwithstanding the apparently undisturbed and continuous character of the original deposition of the strata, that the abrupt transition

from the one facies of fossils to the other must represent a long interval of time which has not been recorded by the deposit of strata. Professor Ramsay, who called attention to these gaps, termed them "breaks in the succession of organic remains." He showed that they occur abundantly among the Palæozoic and Secondary rocks of England. It is obvious, of course, that these breaks, even though traceable over wide regions, were not general over the whole globe. There have never been any universal interruptions in the continuity of the chain of being, so far as geological evidence can show. But the physical changes which caused the breaks may have been general over a zoological district or minor region. They no doubt often caused the complete extinction of genera and species which had a small geographical range.

From all these facts it is clear that the geological record, as it now exists, is at the best but an imperfect chronicle of geological history. In no country is it complete. The lacunae of one region must be supplied from another. Yet in proportion to the geographical distance between the localities where the gaps occur and those whence the missing intervals are supplied, the element of uncertainty in our reading of the record is increased. The most desirable method of research is to exhaust the evidence for each area or province, and to compare the general order of its succession as a whole with that which can be established for other provinces. It is, therefore, only after long and patient observation and comparison that the geological history of different quarters of the globe can be correlated.

Subdivisions of the Geological Record by means of Fossils.—As fossil evidence furnishes a much more satisfactory and widely applicable means of subdividing the stratified rocks of the earth's crust than mere lithological characters, it is made the basis of the geological classification of these rocks. Thus we may find a particular stratum marked by the occurrence in it of various fossils, one or more of which may be distinctive, either from occurring in no other bed above and below, or from special abundance in that stratum. These species might therefore be used as a guide to the occurrence of the bed in question, which might be called by the name of the most abundant species. In this way a geological horizon or zone would be marked off, and geologists would thereafter recognize its exact position in the series of formations. But before such a generalization can be safely made, we must be sure that the species in question really never does appear on any other platform. This evidently demands wide experience over an extended field of observation. The assertion that a particular species occurs only on one horizon manifestly rests on negative evidence as much as on positive. The palæontologist who makes it cannot mean more than that he knows the fossil to lie on that horizon, and that, so far as his own experience and that of others goes, it has never been met with anywhere else. But a single example of the occurrence of the fossil on a different zone would greatly damage the value of his generalization, and a few such cases would demolish it altogether. Hence all such statements ought at first to be made tentatively. To establish a geological horizon on limited fossil evidence, and then to assume the identity of all strata containing the same fossils, is to reason in a circle and to introduce utter confusion into our interpretation of the geological record. The first and fundamental point is to determine accurately the order of superposition of the strata. Until this is done, detailed palæontological classification may prove to be worthless. But when once the succession of the rocks has been fixed palæontological evidence may become paramount.

From what has been above advanced it must be evident that, even if the several groups in a formation or system of rocks in any district or country have been minutely subdivided by means of their characteristic fossils, and if, after

the lapse of many years, no discovery has occurred to alter the established order of succession of these fossils, nevertheless the subdivisions can only be held good for the region in which they have been made. They must not be supposed to be strictly applicable everywhere. Advancing into another district or country where the petrographical characters of the same formation or system indicate that the original conditions of deposit must have been very different, we ought to be prepared to find a greater or less departure from the first observed or what might be regarded as the normal order of organic succession. There can be no doubt that the appearance of new organic forms in any locality has been in large measure connected with such physical changes as are indicated by diversities of sedimentary materials and arrangement. The Upper Silurian formations, for example, as studied by Murchison in Shropshire and the adjacent counties, present a clear sequence of strata well defined by characteristic fossils. But within a distance of 60 miles it becomes impossible to establish these subdivisions by fossil evidence. If we examine corresponding strata in Scotland, we find that they contain some fossils which never rise above the Lower Silurian formations in Wales and the west of England. Again, in Bohemia and in Russia we meet with still greater departures from the order of appearance in the original Silurian area, some of the most characteristic Upper Silurian organisms being there found far down beneath strata replete with records of Lower Silurian life. Nevertheless the general succession of life from Lower to Upper Silurian types remains distinctly traceable. Such facts warn us against the danger of being led astray by an artificial precision of palæontological detail. Even where the palæontological sequence is best established, it rests probably in most cases not merely upon the actual chronological succession of organic forms, but also, far more than is usually imagined, upon original accidental differences of local physical conditions. As these conditions have constantly varied from region to region, it must hardly ever happen that the same minute palæontological subdivisions, so important and instructive in themselves, can be identified and paralleled, except over comparatively limited geographical areas.

It cannot be too frequently stated, nor too prominently kept in view, that, although gaps occur in the succession of organic remains as recorded in the rocks, there have been no such blank intervals in the progress of plant and animal life upon the globe. The march of life has been unbroken, onward and upward. Geological history, therefore, if its records in the stratified formations were perfect, ought to show a blending and gradation of epoch with epoch, so that no sharp divisions of its events could be made. But the progress has been constantly interrupted, now by upheaval, now by volcanic outbursts, now by depression. These interruptions serve as natural divisions in the chronicle, and enable the geologist to arrange his history into periods. As the order of succession among stratified rocks was first made out in Europe, and as many of the gaps in that succession were found to be widespread over the European area, the divisions which experience established for that portion of the globe came to be regarded as typical, and the names adopted for them were applied to the rocks of other and far distant regions. This application has brought out the fact that some of the most marked breaks in the European series do not exist elsewhere, and, on the other hand, that some portions of that series are much more complete than in other regions. Hence, while the general similarity of succession may remain, different subdivisions and nomenclature are required as we pass from continent to continent.

A bed, or limited number of beds, characterized by one or more distinctive fossils, is termed a *zone* or *horizon*, and,

as already mentioned, is often known by the name of a typical fossil, as the different zones in the Lias are by their special species of ammonite. A series of such zones, united by the occurrence among them of a number of the same species or genera, is called a *group*. A series of groups similarly related constitute a *formation*, and a number of formations may be united into a *system*. The terminology employed in this classification will be discussed in the following part.

PART VI.—STRATIGRAPHICAL GEOLOGY.

This branch of the science arranges the rocks of the earth's crust in the order of their appearance, and interprets the sequence of events of which they form the records. Its province is to cull from all the other departments of geology the facts which may be needed to show what has been the progress of our planet, and of each continent and country, from the earliest times of which the rocks have preserved any memorial. Thus from mineralogy and petrography it obtains information regarding the origin and subsequent mutations of minerals and rocks. From dynamical geology it learns by what agencies the materials of the earth's crust have been formed, altered, broken, upheaved, and melted. From structural geology it understands how these materials were put together so as to build up the complicated crust of the earth. From palæontological geology it receives in well-determined fossil remains a clue by which to discriminate the different stratified formations, and to trace the grand onward march of organized existence upon this planet. Stratigraphical geology thus gathers up the sum of all that is made known by the other departments of the science, and makes it subservient to the interpretation of the geological history of the earth.

The leading principles of stratigraphy may be summed up as follows:—

1. In every stratigraphical research the fundamental requisite is to establish the order of superposition of the strata. Until this is accomplished it is impossible to arrange the dates and make out the sequence of geological history.

2. The stratified portion of the earth's crust, or geological record, as it has been termed, may be subdivided into natural groups or formations of strata, each marked throughout by some common genera or species, or by a general resemblance in the type or character of its organic remains.

3. Many living species of plants and animals can be traced downward through the more recent geological formations, but they grow fewer in number as they are followed into more ancient deposits. With their disappearance we encounter other species and genera which are no longer living. These in turn may be traced backward into earlier formations, till they too cease, and their places are taken by yet older forms. It is thus shown that the stratified rocks contain the records of a gradual progression of organic forms. A species which has once died out does not seem ever to have reappeared. But as has been already pointed out in reference to Barrande's doctrine of colonies, a species may within a limited area appear in a formation older than that of which it is characteristic, having temporarily migrated into the district from some neighbouring region where it had already established itself.

4. When the order of succession of organic remains among the stratified rocks has been determined, they become an invaluable guide in the investigation of the relative age of rocks and the structure of the land. Each zone and formation, being characterized by its own species or genera, may be recognized by their means, and the true succession of strata may thus be confidently established even in a country which has been shattered by dislocation, or where the rocks have been folded and inverted.

5. The relative chronological value of the divisions of the geological record is not to be measured by mere depth of strata. While it may be reasonably assumed that a great thickness of stratified rock must mark the passage of a long period of time, it cannot safely be affirmed that a much less thickness elsewhere represents a correspondingly diminished period. This may sometimes be made evident by an unconformability between two sets of rocks, as has already been explained. The total depth of both groups together may be, say 1000 feet. Elsewhere we may find a single unbroken formation reaching a depth of 10,000 feet, but it would be utterly erroneous to conclude that the latter represents ten times the length of time shown by the two former. So far from this being the case, it might not be difficult to show that the minor thickness of rock really denoted by far the longer geological interval. If, for instance, it could be proved that the upper part of both the sections lay on one and the same geological platform, but that the lower unconformable series in the one locality belonged to a far lower and older system of rocks than the base of the thick conformable series in the other, then it would be clear that the gap marked by the unconformability really indicated a longer period than the massive succession of deposits.

6. Fossil evidence furnishes the chief means of comparing the relative value of formations and groups of rock. A break in the succession of organic remains marks an interval of time often unrepresented by strata at the place where the break is found. The relative importance of these breaks, and therefore, probably, the comparative intervals of time which they mark, may be estimated by the difference of the faunas of the fossils on each side. If, for example, in one case we find every species to be dissimilar above and below a certain horizon, while in another locality only half of the species on each side are peculiar, we naturally infer, if the total number of species seems large enough to warrant the inference, that the interval marked by the former break was very much longer than that marked by the second. But we may go further and compare by means of fossil evidence the relation between breaks in the succession of organic remains and the depth of strata between them.

Three formations of fossiliferous strata, A, C, and H, may occur conformably above each other. By a comparison of the fossil contents of all parts of A, it may be ascertained that, while some species are peculiar to its lower, others to its higher portions, yet the majority extend throughout the formation. If now it is found that of the total number of species in the upper portion of A only one-third passes up into C, it may be inferred with some probability that the time represented by the break between A and C was really longer than that required for the accumulation of the whole of the formation A. It might even be possible to discover elsewhere a thick intermediate formation B filling up the gap between A and C. In like manner were it to be discovered that, while the whole of the formation C is characterized by a common suite of fossils, not one of the species and only one half of the genera pass up into H, the inference could hardly be resisted that the gap between the two formations marks the passage of a far longer interval than was needed for the deposition of the whole of C. And thus we reach the remarkable conclusion that, thick though the stratified formations of a country may be, in some cases they may not represent so long a total period of time as do the gaps in their succession,—in other words, that non-deposition was more frequent and prolonged than deposition, or that the intervals of time which have been recorded by strata have not been so long as those which have not been so recorded.

In all speculations of this nature, however, it is necessary to reason from as wide a basis of observation as possible, seeing that so much of the evidence is negative. Especially

needful is it to bear in mind that the cessation of one or more species at a certain line among the rocks of a particular district may mean nothing more than that, owing to some change in the conditions of life or of deposition, these species were compelled to migrate or became locally extinct at the time marked by that line. They may have continued to flourish abundantly in neighbouring districts for a long period afterward. Many examples of this obvious truth might be cited. Thus in a great succession of mingled marine, brackish-water, and terrestrial strata, like that of the Carboniferous Limestone series of Scotland, corals, crinoids, and brachiopods abound in the limestones and accompanying shales, but disappear as the sandstones, ironstones, clays, coals, and bituminous shales supervene. An observer meeting for the first time with an instance of the disappearance, and remembering what he had read about "breaks in succession," might be tempted to speculate about the extinction of these organisms, and their replacement by other and later forms of life, such as the ferns, lycopods, ganoid fishes, and other fossils so abundant in the overlying strata. But further research would show him that high above the plant-bearing sandstones and coals other limestones and shales might be observed, once more charged with the same marine fossils as before, and still farther overlying groups of sandstones, coals, and carbonaceous beds followed by yet higher marine limestones. He would thus learn that the same organisms, after being locally exterminated, returned again and again to the same area. After such a lesson he would probably pause before too confidently asserting that the highest bed in which we can detect certain fossils marked really their final appearance in the history of life. A break in the succession may thus be extremely local, one set of organisms having been given to a different part of the same region, while another set occupied their place until the first was enabled to return.

7. The geological record is at the best but an imperfect chronicle of the geological history of the earth. It abounds in gaps, some of which have been caused by the destruction of strata owing to metamorphism, denudation, or otherwise, some by original non-deposition, as above explained. Nevertheless from this record alone can the progress of the earth be traced. It contains the registers of the births and deaths of tribes of plants and animals which have from time to time lived on the earth. But a small proportion of the total number of species which have appeared in past time have been thus chronicled, yet by collecting the broken fragments of the record an outline at least of the history of life upon the earth can be deciphered.

The nomenclature adopted for the subdivisions of the geological record bears witness to the rapid growth of geology. It is a patch-work in which no system nor language has been adhered to, but where the influences by which the progress of the science has been moulded may be distinctly traced. Some of the earliest names are lithological, and remind us of the fact that mineralogy and petrography preceded geology in the order of birth.—Chalk, Oolite, Greensand, Millstone Grit. Others are topographical, and often recall the labours of the early geologists of England—London Clay, Oxford Clay, Purbeck, Portland, Kimridge beds. Others are taken from local English provincial names, and remind us of the debt we owe to William Smith, by whom so many of them were first used.—Lias, Gault, Crag, Cornbrash. Others of later date recognize an order of superposition as already established among formations—Old Red Sandstone, New Red Sandstone. By common consent it is admitted that names taken from the region where a formation or group of rocks is typically developed, are best adapted for general use. Cambrian, Silurian, Devonian, Permian, Jurassic, are of this class, and have been adopted all over the globe.

and serpentine. But perhaps their most intelligible sections are those which they present in Bavaria and Bohemia between the valley of the Danube and the headwaters of the Elbe. They are there divided into two well-marked groups—(a) red gneiss, covered by (b) grey gneiss. According to Gumbel the former (called by him the Bojan gneiss) may be traced as a distinct formation associated with granite, but with very few other kinds of crystalline or schistose rocks, while the latter (termed the Hercynian gneiss) consists of gneiss with abundant interstratification of many other schistose rocks, graphitic limestone, and serpentine. The Hercynian gneiss is overlaid by mica-schist, above which comes a vast mass of argillaceous schists and shales. Gumbel some years ago found in the marbles associated with the younger gneiss what he considered to be an organism of the same genus as the *Eozoon* of Canada, to which reference will immediately be made. He named it *Eozoon Bavaricum*. More recently a similar substance was obtained in the Archæan series of Bohemia, and named by Fritsch *Eozoon Bohemicum*.

AMERICA.—In North America Archæan rocks cover a large part of the continent from the Arctic Circle southwards to the great lakes. They appear likewise, as in Europe, along the central parts of prominent mountain chains, as in the Rocky Mountain range and that of the Appalachians. They have been carefully studied in Canada, where the late Sir W. E. Logan, Director of the Geological Survey of the Dominion, estimated their depth at about 30,000 feet, but neither their top nor their base can there be found. He named them the Laurentian system from their abundant development along the shores of the St. Lawrence. They have been divided into two series—(1) a lower formation more than 20,000 feet thick, consisting chiefly of granitic, orthoclase gneiss, with bands of quartz-rock, schists, iron-ore, and limestone, and (2) an upper formation fully 10,000 feet thick, composed also, for the most part, of gneiss, but marked by the occurrence of bands of Labrador felspar, as well as schist, iron-ore, and limestone. The upper division has been stated to lie unconformably on the lower. Mr. Selwyn, however, has recently pointed out that this is almost certainly not the case, but that the limestone-bearing series rests conformably upon a massive granuloid gneiss, to which he would restrict the term Laurentian, classing the limestones in the next or Huronian system (*Nat. Hist. Soc. Montreal*, Feb. 1879).

In one of the Laurentian limestones of Canada, specimens have been found of a remarkable mixture of calcite and serpentine. These minerals are arranged in alternate layers, the calcite forming the main framework of the substance with the serpentine (sometimes loganite, pyroxene, &c.) disposed in thin, wavy, inconstant layers, as if filling up flattened cavities in the calcareous mass. So different from any ordinary mineral segregation with which he was acquainted did this arrangement appear to Logan, that he was led to regard the substance as probably of organic origin. This opinion was adopted, and the structure of the supposed fossil was worked out in elaborate detail by Dr. Dawson of Montreal, who pronounced the organism to be the remains of a massive foraminifer which he called *Eozoon*, and which he believed must have grown in large thick sheets over the sea-bottom. This opinion was confirmed by Dr. W. B. Carpenter, who from a large suite of additional and better preserved specimens, described a system of internal canals having the characters of those in true foraminiferal structures. (See FORAMINIFERA.) Other observers, notably Professors King and Rowney of Galway and Möbius of Kiel, have opposed the organic nature of *Eozoon*, and have endeavoured to show that the supposed canals and passages are merely infiltration veinings of serpentine in the calcite. In some cases, however, the "canal-

system" is not filled with serpentine but with dolomite, which seems to show that the cavities must have existed before either dolomite or serpentine were introduced into the substance. Dr. Carpenter contends that the disposition of these passages in his decalcified specimens is very regular, and quite unlike any mineral infiltration with which he is acquainted.

The opinion of the organic nature of *Eozoon* has been supposed to receive support from the large quantity of graphite found throughout the Archæan rocks of Canada and the northern parts of the United States. This mineral occurs partly in veins, but chiefly disseminated in scales and laminae in the limestones and as independent layers. Dr. Dawson estimates the aggregate amount of it in one band of limestone in the Ottawa district as not less than from 20 to 30 feet, and he thinks it is hardly an exaggeration to say that there is as much carbon in the Laurentian as in equivalent areas of the Carboniferous system. He compares some of the pure bands of graphite to beds of coal, and maintains that no other source for their origin can be imagined than the decoxidation of carbonic acid by living plants. In the largest of three beds of graphite at St. John he has found what he considers may be fibrous structure indicative of the existence of land-plants.

Still further evidence in favour of organized existence during Archæan time in the North American area has been adduced from the remarkably thick and abundant masses of iron ore associated with the Laurentian rocks of Canada and the United States. Dr. Sterry Hunt has called attention to these ores as proving the precipitation of iron by decomposing vegetation during the Laurentian period on a more gigantic scale than at any subsequent geological epoch.¹ Some of the beds of magnetic iron ranged up to 200 feet in thickness. Large masses also of hematite and titaniferous iron, as well as of iron sulphides, occur in the Canadian Archæan series. These great bands of iron ore run southward, and form an important feature in the economic geology of the Northern States of the Union.

Above the Laurentian rocks in the region of Lake Huron lies a vast mass of slates, conglomerates, limestones, and quartz-rocks, attaining a depth of from 10,000 to 20,000 feet. They are termed Huronian. No fossils have yet been found in them; but they must be much younger than the Laurentian rocks, on which they rest unconformably, and from which they have been in part at least derived.

II. PALÆOZOIC

Under the general term of Primary or Palæozoic are now included all the older sedimentary formations containing organic remains, up to the top of what is termed the Permian system. These rocks consist mainly of sandy and muddy sediment with occasional intercalated zones of limestone. They everywhere bear witness to comparatively shallow water and the proximity of land. Their frequent alternations of sandstone, shale, conglomerate, and other detrital materials, their abundant, rippled, and sun-cracked surfaces marked often with burrows and trails of worms, as well as the prevalent character of their organic remains, show that they must have been deposited in areas of slow subsidence, bordering continental or insular masses of land. As regards the organisms of which they have preserved the casts, the Palæozoic rocks, as far as the present evidence goes, may be grouped into two divisions—an older and a newer—the former distinguished more especially by the abundance of its graptolitic, trilobitic, and brachiopodous fauna, and by the absence of vertebrate remains; the latter by the number and variety of its fishes and amphibians, the

¹ *Geology of Canada*, 1863, p. 573.

disappearance and extinction of graptolites and trilobites, and the abundance of its cryptogamic terrestrial flora

CAMBRIAN.

This name was applied by Sedgwick to the rocks of North Wales (Cambria), where he first investigated them. Their base is there nowhere seen, so that, though they attain a great depth, some part of their total mass must be concealed from view. They pass up continuously into the base of the Silurian system. Considerable diversity of opinion has existed, and still continues, as to the line where the upper limit of the Cambrian system should be drawn. Murchison contended that this line should be placed below the strata where a trilobitic and brachiopodous fauna begins, and that these strata cannot be separated from the overlying Silurian system. He therefore included in the Cambrian only the barren grits and slates of the Longmynd, Harlech, and Llanberis. Sedgwick, on the other hand, insisted on carrying the line up to the base of the Upper Silurian rocks. He thus left these formations as alone constituting the Silurian system, and massed all the Lower Silurian in his Cambrian system. Murchison worked out the stratigraphical order of succession from above, and chiefly by help of organic remains. He advanced from where the superposition of the rocks is clear and undoubted, and for the first time in the history of geology ascertained that the "transition-rocks" of the older geologists could be arranged into zones by means of characteristic fossils as satisfactorily as the Secondary formations had been classified in a similar manner by William Smith. Year by year, as he found his Silurian types of life descend farther and farther into lower deposits, he pushed backward the limits of his Silurian system. In this he was supported by the general consent of geologists and paleontologists all over the world. Sedgwick, on the other hand, attacked the problem rather from the point of stratigraphy and geological structure. Though he had collected fossils from many of the rocks of which he had made out the true order of succession in North Wales, he allowed them to be for years unexamined. Meanwhile Murchison had studied the prolongations of some of the same rocks into South Wales, and had obtained from them the abundant suite of organic remains which characterized his Lower Silurian formations. Similar fossils were found abundantly on the continent of Europe, and in America. Naturally the classification proposed by Murchison was adopted all over the world. As he included in his Silurian system the oldest rocks containing a distinctive fauna of trilobites and brachiopods, the earliest fossiliferous rocks were everywhere classed as Silurian, and the name Cambrian was discarded by geologists of other countries as indicative of a more ancient series of deposits not characterized by peculiar organic remains, and therefore not capable of being elsewhere satisfactorily recognized. Barrande, investigating the most ancient fossiliferous rocks of Bohemia, distinguished by the name of the "Primordial Zone" a group of strata underlying the Lower Silurian rocks, and containing a peculiar and characteristic suite of trilobites. He classed it, however, with the Silurian system, and Murchison adopted the term, grouping under it the lowest dark slates which in Wales and the border English counties contained some of the same early forms of life.

Investigations during the last twelve years, however, chiefly by the late Mr Salter and Mr Hicks, have brought to light a much more abundant fauna from the so-called primordial rocks of Wales than they were supposed to possess. These fossils were found to be in large measure distinct from those in the undoubted Lower Silurian rocks. Thus the question of the proper base of the Silurian system was re-opened, and the claims of the Cambrian system to a

great upward extension were more forcibly urged than ever. But these claims could now be urged on paleontological evidence such as had never before been produced. Accordingly there has arisen a general desire among the geologists of Britain to revise the nomenclature of the older rocks. Though as yet a common accord of opinion has not been reached, there seems a strong probability that ultimately the boundary line between the Cambrian and Silurian systems will be drawn above the primordial zone along the base of the great Arenig group or Lower Llandeilo rocks of Murchison. All his Silurian strata of older date than these rocks will be classed as Cambrian.

According to this classification, the Cambrian system, as developed in North Wales and the border English counties, consists of purple, reddish-grey, and green slates, grits, sandstones, and conglomerates. Its true base is nowhere seen, yet even the visible mass of strata has been estimated to reach the enormous thickness of 25,000 feet. By far the larger part of this vast depth of rock is unfossiliferous. Indeed it is only in some bands of the upper 6000 feet, or thereabouts, that fossils occur plentifully. By fossil evidence the Cambrian system may be divided into Lower and Upper, and each of these sections may be further subdivided into two groups, as in the following table:—

Cambrian of Wales	{	Upper	{ 4 Tremadoc slates 3 Llangula flags
		Lower	{ 2 Menevenian group 1 Harlech and Longmynd group

1. *Harlech and Longmynd Group*—This includes purple, red, and grey flags, sandstones, and slates, with conglomerates. These strata attain a great thickness, estimated at 4000 feet in South Wales, but more than 8000 in North Wales. They were formerly supposed to be nearly barren of organic remains; but in recent years, chiefly through the researches of Mr Hicks at St David's, they have yielded a tolerably abundant fauna, consisting of 80 species. Among these are 16 species of trilobite (*Pandora*, *Platystrophia*, *Micradiscus*, *Palaopogon*, *Agnostus*, *Conocozygus*), four annelids (*Arenicola*), a sponge (*Protospongia*), five brachiopods (*Dicranus*, *Lingulella*), two pteropods (*Thea*), &c. Many of the surfaces of the strata in some parts of this group are marked with ripples, sun-cracks, and rain-pittings as well as with trails of worms—indicative of shallow-water and shore-conditions of deposit. 14 of the 30 species, according to Mr Etheridge, F.R.S., pass up into the Menevenian group, and 7 continue into the Llangula flags.

2. *Menevenian Group*—This subdivision has been proposed for a series of sandstones and shales, with dark-blue slates and flags, dark-grey flags and grey grits, which are seen near St David's (Menervia), where they attain a depth of about 600 feet. They pass down conformably into the Harlech group with which, as just stated, they are connected by 14 species in common. The Menevenian beds have yielded upwards of 50 species of fossils, of which 24 are confined to the Menevenian, while 18 pass up into the lower Llangula flags. Among these the trilobites are especially prominent. Some of them attained a great size, *Pandora* *Daviesi* being nearly two feet long. But with these were mingled others of diminutive size. It is noteworthy also, as Mr Hicks has pointed out, that while the trilobites had attained their maximum size at this early period, they are represented among the other Cambrian rocks by genera indicative of almost every stage of development, "from the little *Agnostus* with two rings in the thorax, and *Micradiscus* with four, to *Bolus* with twenty-four," while blind genera occur together with those having the largest eyes. Upwards of 30 species of trilobites have been obtained from the Menevenian beds, the genera *Agnostus* (7 species), *Conocozygus* (7 species), and *Pandora* *Daviesi* being especially characteristic. Four species of sponges (*Protospongia*) and some annelid-tracks likewise occur. The mollusca are represented by 6 species of brachiopods of the genera *Dicranus*, *Lingulella*, and *Obolus*; 5 pteropods (*Thea*) have been met with. The earliest entomostacea (*Entomois*) and the first crustacean (*Protocystis*) yet discovered occur in the Menevenian fauna.

3. *Llangula Flags*—These strata, consisting of bluish and black slates and flags, with bands of grey flags and sandstones, attain in some parts of Wales a thickness of more than 5000 feet. They received their name from the discovery by Mr E. Davis (1846) of vast numbers of a *Lingula* (*Lingulella* *Daviesi*) in some of their layers. They rest conformably upon, and pass down into, the Menevenian beds below them, and likewise graduate into the Tremadoc group above. They are distinguished by a characteristic

¹ Hicks, *Quart. Jour. Nat. Geol. Soc.* xxvii. 174

suite (78 species) of organic remains. The trilobites include the genera *Agnostus*, *Acrocephalus*, *Conocozyphus*, *Dalmanella*, *Elmurus*, *Olenus*, and *Paradoxides*. The earliest phyllopo-*d*s (*Hypocoryphus*) and heteropods (*Bellerophon*) occur in these beds. The brachiopods include species of *Lingulella* (*L. Davisii*), *Discalia*, *Obolella*, and *Orthis*. The pteropods are represented by three species of *Theca*. Several annelides (*Cirratulus*) and polychaetes (*Rensselaeria*) likewise occur.

According to a careful census by Mr Etheridge, the Lingula zone may be grouped into three zones, each characterized by a peculiar assemblage of organic remains. The lower division contains 87 species, of which 9 are peculiar to it. The middle zone has yielded 5 species, 2 of which (*Conocozyphus bucephalus* and *Lingulella Davisii*) pass down into the lower division, 1 (*Elongatus euagata*) into the upper, and 2 (*Lingula squamosa* and *Bellerophon Cambiensis*) are peculiar. The upper zone has yielded 40 species. Of these 9 pass up into the Tremadoc beds, while 3 (*Lingulella lepis* and *L. Davisii*) continue on into the Arenig group. 4. *Tremadoc Slates*.—This name was given by Sedgwick to a group of dark grey slates, about 1000 feet thick, found near Tremadoc in Carnarvonshire, and traceable thence to Dolgelly. Their importance as a geological formation was not recognized until the discovery of a remarkably abundant and varied fauna in them. They contain the earliest crinoids, star-fishes, lamellibranchs, and cephalopods yet found. The trilobites embrace 14 genera, among which, besides some, as *Agnostus*, *Conocozyphus*, and *Olenus*, found in the Lingula flags, we meet for the first time with *Aspidaria*, *Asaphus*, *Chonetes*, *Neurocrinus*, *Stropheodonta*, *Palaeophylus*, &c. The same genera, and in some cases species, of brachiopods appear which occur in the Lingula flags, *Orthis Curvispinis* and *Lingulella Davisii* being common forms. Mr Hicks has described 12 species of lamellibranchs from the Tremadoc beds of Ramsey Island and St David's, belonging to the genera *Oenodonta*, *Pelecypoda*, *Glyptorthis*, *Davidia*, and *Melolobos*. The cephalopods are represented by *Orthoceras syriacum* and *Cyrtoceras piceum*, the pteropods by *Theca Davisii*, *T. operculata*, and *Conchulus Houghii*, the echinoderms by a beautiful star-fish (*Palastridium tansugetum*) and by a crinoid (*Dendrocrinus Cambiensis*).¹

Careful analysis of the fossils yielded by the Tremadoc beds suggests a division of this formation into two zones. According to a census by Mr Etheridge, the Lower Tremadoc rocks have yielded in all 56 species, of which 9 pass down into the Lingula flags and 10 ascend into the Upper Tremadoc zone, 31 being peculiar. The Upper Tremadoc beds contain, as at present ascertained, 33 species, of which 9 are peculiar, and 13 or possibly 15 pass up into the Arenig group. It is at the top of the Upper Tremadoc strata that the line between the Cambrian and Silurian systems is here drawn. According to Professor Ramsay, there is evidence of a physical break at the top of the Tremadoc beds of Wales, so that on a large scale the next succeeding or Arenig strata repose unconformably upon everything older than themselves. Mr Etheridge also shows that the paleontological break is nearly complete, only about 7 per cent. of the fossils of the one series passing over into the other. Out of 184 known Arenig species, not more than 13 are common to the Tremadoc beds underneath. Besides these important facts the character of the Arenig fauna strongly distinguishes it from that of the formations below, and further supports the line of division here adopted between the Cambrian and Silurian systems.

In the north-west of Scotland a mass of reddish-brown and chocolate-coloured sandstone and conglomerate (at least 8000 feet thick in the Loch Torridon district) lies unconformably upon the fundamental gneiss in nearly horizontal or gently inclined beds. It rises into picturesque groups of mountains which stand out as striking monuments of denudation, seeing that the truncated ends of their component flat strata can be traced even from a distance forming parallel bars along the slopes and precipices. The denudation must have been considerable even in early Silurian times, for the sandstones are unconformably overlaid by quartz-rocks and limestones containing Lower Silurian fossils. No trace of organic remains of any kind has been found in the red sandstones themselves. They were at one time regarded as Old Red Sandstone, though Macculloch,

and afterwards Hay Cunningham, pointed out that they underlie parts of the schistose rocks of the northern Highlands. The discovery by Mr C. W. Peach of Lower Silurian shells in the overlying limestones showed that the massive red sandstones of western Ross and Sutherland could not be paralleled with those of the eastern tracts of those counties, but must be of older date than part of the Llandello rocks of the Lower Silurian period. Sir R. Murchison classed them as Cambrian—an identification which has much support in the lithological resemblance between these rocks of the north-west Highlands and much of the Lower Cambrian system of Wales.

In the south-east of Ireland masses of purplish, red, and green shales, slates, grits, quartz-rocks, and schists occupy a considerable area and attain a depth of 14,000 feet without revealing their base, while their top is covered by unconformable formations (Lower Silurian and Lower Carboniferous). They have yielded *Oldhamia*, described originally as a setularian zoophyte, but now regarded by many paleontologists as an alga, also numerous burrows and trails of annelides (*Histiaderma Tiberium*, *Arenolites didymus*, *A. sparsus*, *Elmingtonia pectini*). No Upper Cambrian forms have been met with in these Irish rocks, which are therefore placed with the Lower Cambrian, the unconformability at their top being regarded as equivalent to the interval required for the deposition of the intervening formations up to the time of the Llandello rocks, as in the north-west of Scotland. Some portions of the Irish Cambrian series have been intensely metamorphosed. Thus on the Howth coast they appear as schists and quartz-rocks; in Wexford they pass into gneiss and granite. In West Galway Mr Kinnaird has described a vast mass of schists, quartz-rocks, and limestones (8000 feet and upwards) passing up into schistose, hornblende, and unaltered rocks containing Llandello fossils, and he agrees with Griffith and King in regarding these as probably Cambrian. He suggests that they are Upper Cambrian, which would imply that Upper Cambrian rocks pass conformably into the Llandello formation without the occurrence of the thick Arenig rocks of Wales. In a difficult country, however, broken by faults and greatly metamorphosed, an unconformability might easily escape detection.

CONTINENTAL EUROPE.—According to the classification adopted by M. Barrande, the older Palaeozoic rocks of Europe suggest an early division of the area of this continent into two regions or provinces,—a northern province, embracing the British Islands, and extending through North Germany into Scandinavia, on the one hand, and into Russia on the other, and a central-European province, including Bohemia, France, Spain, Portugal, and Sardinia.

Bohemia.—The classic researches of M. Barrande have given to the oldest fossiliferous rocks of Bohemia an extraordinary interest. He has made known the existence there of a remarkable suite of organic remains representative of those which characterize the Cambrian rocks of Britain. At the base of the geological formations of that region lie the Archean gneisses already described. These are overlaid by vast masses of schists, conglomerates, quartzites, slates, and igneous rocks, which have been more or less metamorphosed, and are singularly barren of organic remains, though some of them have yielded traces of annelides. They pass up into certain grey and green fissile shales, in which the earliest well-marked fossils occur. The organic contents of this zone (Etage C) form what M. Barrande terms his primordial fauna, which contains 40 or more species, of which 27 are trilobites, belonging to the characteristic Cambrian genera—*Paradoxides* (12), *Agnostus* (5), *Conocozyphus* (4), *Ellipsorephalus* (2), *Hydrocephalus* (2), *Arionellus* (1), *Sao* (1). Not a single species of any one of these genera, save *Agnostus* (of which 4 species

¹ Hicks, *Quart. Journ. Geol. Soc.*, vol. 39.

appear in the second fauna), has been found by M. Barrande higher than his primordial zone. Among other organisms in this primordial fauna, the brachiopods are represented by 2 species (*Orthis* and *Obolus*), the pteropods by 5 (*Theca*), and the eelindoderms by 5 cystideans.

Scandinavia.—In Norway the vast masses of Archean gneiss (Tellemark) are overlaid by schists, red sandstones, and conglomerates. These are termed the Sparagmite formation, and have hitherto proved barren of fossils. They are covered, however, by beds containing *Dictyonema Norvegicum*, which may represent the primordial zone of Barrande. In Sweden the sparagmite formation has been more productive of organic remains. It is there represented by a sandy zone not more than 50 or 60 feet thick—a poor equivalent for the great mass of strata in the Cambrian system of Wales. It was originally termed the *Regio Fucularum* by Angelin, from the fucoids alone found in it. In more recent years, however, its list of organic remains has been considerably increased; 12 species of plants, chiefly fucoids, but including some (*Eophyton*) of higher grade, 9 species of annelides, 4 brachiopods, a pteropod, a bryozoan, a coral, a crinoid, and a sponge have been obtained. Above the strata containing these organisms comes a zone which has yielded 77 species of primordial trilobites, including the genera *Agnostus* (19 species), *Conocoryphe* (13), *Olenus* (21), *Paradoxides* (9).

NORTH AMERICA.—Rocks corresponding in position and in the general character of their organic contents with the Cambrian formations of Britain have been recognized in different parts of the United States and Canada. They appear in Newfoundland, whence, ranging by Nova Scotia and New Brunswick, they enter Canada, the northern parts of New York, Vermont, and eastern Massachusetts. They rise again along the Appalachian ridge, in Wisconsin, Minnesota, Missouri, Arkansas, Texas, and Georgia. Westward from the great valley of the Mississippi, where they have been found in many places they reappear from under the Secondary and younger Paleozoic rocks of the Rocky Mountains. They have been divided by American geologists into two formations—(1) Acadian, a mass (2000 feet) of grey and dark shales and some sandstones; and (2) Potsdam (or Georgian), which attains in Newfoundland a depth of 5600 feet, but thins away westward and southward till in the valley of the St Lawrence, where it was studied by Logan and his associates of the Geological Survey of Canada, it is only from 300 to 600 feet thick.

Among the organic remains of the North American Cambrian rocks fucoid casts appear in many of the sandstones, but no traces of higher vegetation. The Acadian formation has yielded primordial trilobites of the genera *Paradoxides*, *Conocoryphe*, *Agnostus*, and some others, brachiopods of the genera *Lingulella*, *Ducina*, *Obolus*, and *Orthis*; and several kinds of annelide-tracks. The Potsdam rocks contain a few sponges, the earliest forms of graptolite, some brachiopods, including, besides the genera in the Acadian beds, *Obolus*, *Camarrella*, and *Orthosina*, some pteropods (*Hyalites* or *Theca*), two species of *Orthoceras*, annelide tracks, trilobites of the genera *Conocoryphe*, *Agnostus*, *Dikelocephalus*, *Olenellus*, *Ptychaspis*, *Chelonicophalus*, *Aglaaspis*, and *Altenurus*.

M. Barrande has called attention to the remarkable uniformity of character in the organic remains of his primordial zone over the continents of Europe and America. He published in 1871 the subjoined table, to show how close is the parallelism between the proportions in which the different classes of the animal kingdom are represented.¹

Countries	Trilobites	Other Crustacea	Crustacea		Mollusks	Invertebrate Classes		Total by Countries

SILURIAN

The important system of rocks next to be described was first investigated by the late Sir R. Murchison in Wales and the bordering counties of England. He found it to be characteristically developed over the tract once inhabited by the Silures, an ancient British tribe, and he thence chose the name of Silurian as a convenient designation. It there passes down conformably into the Tremadoc slates at the top of the Cambrian series, and is covered conformably by the base of the Old Red Sandstone.

GREAT BRITAIN.—In the typical area where Murchison's discoveries were first made he found the Silurian rocks divisible into two great and well-marked series, which he termed Lower and Upper. This classification has been found to hold good over a large part of the world. The subjoined table shows the present arrangement and nomenclature of the various subdivisions of the Silurian system.

		Feet
B Upper Silurian.	(7) Ludlow group	1,850
	(6) Wenlock group	1,600
	(5) Upper Llandovery group	1,500
	(4) Lower Llandovery group	1,000
A Lower Silurian	(3) Bala and Cadoc group	6,000
	(2) Llandovery group	2,500
	(1) Arenig or Stiper Stone group	4,000

Approximate average thickness = 18,550

A. Lower Silurian

1. *Arenig or Stiper Stone Group*.—These rocks consist of dark slates, shales, flags, and bands of sandstone. They are abundantly developed in the Arenig mountain, where, as originally described by Sedgwick, they contain masses of associated porphyry. Throughout that district they have been deposited at a time when streams of lava and showers of volcanic ashes were thrown out in great quantity from submarine vents. They contain an abundant suite of organic remains (184 species), of which only 13 species are common to the Tremadoc beds below. Trilobites occur of the genera *Aglina*, *Agnostus*, *Ampyx*, *Barrandeia*, *Calymene*, *Chevrurus*, *Ilcanopsis*, *Ilucnus*, *Ogygia*, *Phacops*, and *Trunculus*. Three species of pteropods (*Conularia*, *Theca*), 18 species of brachiopods (*Lingula*, *Lingulella*, *Obolus*, *Ducina*, *Siphonotretia*, *Orthis*), 8 lamellibranchs, 3 gasteropods, and 5 cephalopods have been found; but the most abundant organisms are the graptolites, of which the Arenig rocks of St David's, in Pembrokeshire, have yielded 48 species, which belong to 20 genera, including *Didymograptus*, *Tetragraptus*, *Diplograptus*, *Dendrograptus*, and *Callograptus*.² Altogether

¹ *Trilobites*, Pague, 1871, p 196. Since the publication of this table the progress of research has increased the number of species from some localities; but the general facts of the primordial fauna has not been materially affected thereby.

² Hicks, *Quart Journ. Geol. Soc.*, xxxi 167; Hopkinson and Lapworth, *ibid.*, p 635.

78 species of hydrozoa have been obtained from the British Arenig rocks, but none from any older strata. This sudden and great development of these organisms gives a distinctive aspect to the Arenig rocks. It continues in the overlying Llandoilo group, so that the graptolites form in Britain a convenient character by which to mark off the Cambrian from the Lower Silurian fauna.

2. *Llandoilo Flag Group*.—Dark argillaceous flagstones, sandstones, and shales, some parts often calcareous. These beds were first described by Murchison as occurring at Llandoilo, in Carmarthenshire. They reappear on the coast of Pembrokeshire, and at Bwlth, in Radnorshire. Up to the present time they have yielded 227 species of fossils. Of these 13 are common to the Arenig below, 82 to the Caradoc or Bala above, while 145 are peculiar. The hydrozoa are still the most abundant forms, 94 species being here met with, no fewer than 81 of these being confined to Llandoilo rocks, and only 9 passing down into the Arenig group. Of crustacea 44 species have been obtained. These include the characteristic trilobites—*Ampyx nudus*, *Asaphus tyrannus*, *Barrandea Cordui*, *Calymene duplicata*, *C. Cambrensis*, *Cheirurus Sedgwicki*, *Ogygia Buchii*, *Trinaculus concentricus*, *T. Lloydii*. The brachiopods number 37 species, including the genera *Orthis*, *Leptæna*, *Strophomena*, *Leptæna*, *Siphonotreta*. The lamellibranchs are represented by 6 species, the gastropods by 10 (*Murchisonia*, *Cyclonema*, *Loxonema*), the heteropods by 7 (*Belterophon*), the pteropods by 2 (*Conularia*, *Theca*), the cephalopods by 8 (*Orthoceras*, *Cyrtoceras*).

A remarkable feature in the history of the Llandoilo rocks in Britain was the outbreak of volcanic action abundantly in North Wales and in Cumberland. Vast piles of lava and ashes were thrown out, which even to this day remain in mass sufficient to form groups of important hills, as Cader Idris, Aran Mowddwy, the Arenigs, and the Moelwyns in Wales, and Helvellyn and Seaw Fell in Westmoreland and Cumberland.

3. *Caradoc or Bala Group*.—Under this name are placed the thick yellowish and grey sandstones of Caer Caradoc in Shropshire, and the grey and dark slates, grits, and sandstones round Bala in Merionethshire. In the Shropshire area some of the rocks are so shelly as to become strongly calcareous. In the Bala district the strata contain two limestones separated by a sandy and slaty group of rocks 1400 feet thick. The lower or Bala limestone (25 feet thick) has been traced as a variable band over a large area in North Wales. It is usually identified with the Coniston limestone of the Westmoreland region. The upper or Hirnant limestone (10 feet) is more local. Bands of volcanic tuff and large beds of various felsitic lavas occur among the Bala beds, and prove the contemporaneous ejection of volcanic products. These attain a thickness of several thousand feet in the Snowdon region.

A large suite of fossils has been obtained from this formation:—the sponges represented by *Sphaerosporgia* and other genera; the graptolites by *Diplograptus pristis*, *Graptolithus pristis*, and *G. Sedgwicki*, &c.; the corals by species of *Helolites*, *Favosites*, *Monticulipora*, *Illyites*, *Petraia*; the echinoderms by encrinurids of the genera *Cyathocrinus* and *Glyptocrinus*, by cystideans of the genera *Echinospirifer* and *Sphenonites*, and by star-fishes of the genera *Palauster* and *Stenaster*; the annelids by *Serpulites*, *Tentaculites*, and numerous burrows and tracks; the trilobites by many species of the genera *Phacops*, *Cheirurus*, *Cybele*, *Lichas*, *Acidaspis*, *Calymene*, *Remopleuridea*, *Asaphus*, *Altenus*, *Ampyx*, and *Trinaculus*; the polyzoa by *Fenestella*, *Glaucanome*, and *Ptilodictya*; the brachiopods

by *Atrypa*, *Rhynchonella*, *Leptæna*, *Orthis* (many species), *Strophomena*, *Ducina*, and *Leptæna*, the lamellibranchs by *Modiolopsis*, *Mytilus*, *Palæarca*, *Pterinea*, *Orthonota*, and *Ctenodonta*; the gastropods by *Murchisonia*, *Pleurotomaria*, *Raphistoma*, *Cyclonema*, *Eumphalus*, *Maclurea*, *Holopea*, the pteropods by *Conularia*, *Theca*, and *Ecutoriphallus*; the heteropods by various species of *Belterophon*, and the cephalopods by many species of *Orthoceras*, with forms of *Cyrtoceras* and *Lutites*.

4. *Lower Llandoilo Group*.—In North Wales the Bala beds about 5 miles S.E. of Bala Lake begin to be covered with grey grits, which gradually expand southwards until they attain a thickness of 1000 feet in South Wales. These overlying rocks are well displayed near the town of Llandoilo, where they contain some conglomerate bands, and where Mr Aveline detected an unconformability between them and the Bala group below them, so that the subterranean movements had already begun, which in Wales marked the close of the Lower Silurian period. Elsewhere they seem to graduate downwards conformably into that group. They cover a considerable breadth of country in Cardigan and Carmarthenshire, owing to the numerous undulations into which they have been thrown. Their chief interest lies in the transition which they present between the fauna of the Lower and Upper Silurian formations. They have yielded in all about 128 species of fossils, whereof 11 are peculiar, 93 are common to the Bala group below, and 83 pass up into Upper Llandoilo rocks above. Some of the peculiar fossils are *Medulites furvus*, *Meristella crassa*, *M. angustifrons*, and *Murchisonia angulata*. Among the forms which come up into the Bala group and disappear here are the corals *Helolites interstinctus*, *Petraia subduplicata*, and *Favosites aspera*; the trilobites *Lichas luvatus* and *Illymus Bownmanni*; the brachiopods *Orthis Aconia* and *O. insularis*; the gastropods *Murchisonia gyrogonia* and *Cyclonema crebristrata*; and the cephalopod *Orthoceras tenuicinctum*. But many of the Lower Silurian forms continue on into the Upper Llandoilo beds. From the abundance of the peculiar brachiopods termed *Pentamerus* in the Lower, but still more in the Upper Llandoilo rocks, these strata were formerly grouped together under the name of "Pentamerus beds." Though the same species are found in both divisions, *Pentamerus oblongus* is chiefly characteristic of the upper group and comparatively infrequent in the lower, while *Stricklandina* (*Pentamerus*) *lens* abounds in the lower but appears more sparingly in the upper.

The Lower Silurian rocks, typically developed in Wales, extend over nearly the whole of Britain, though largely buried under more recent formations. They rise into the hilly tracts of Westmoreland and Cumberland, where they consist of the following subdivisions in descending order:—

(Lower Llandoilo not represented)	
Coniston Limestone and Shale	= Bala beds.
Volcanic series, tuffs and lavas without any interstratification of ordinary sedimentary strata except at the base, 12,000 ft ...	= Part of Bala, whole of Llandoilo, and part of Aberg formation.
Skiddaw Slates, 10,000 or 12,000 ft base not seen	= Arenig, with perhaps Tremadoc and Llandoilo Flags.

Apart from the massive intercalation of volcanic rocks these strata present considerable lithological and palæontological differences from the typical subdivisions in Wales. The Skiddaw slates are black or dark-grey argillaceous, and in some beds sandy rocks, often much cleaved though seldom yielding workable slates, sometimes soft and black like Carboniferous shale. As a rule they are altered portions they have yielded about 40 species of graptolites (chiefly of the genera *Diplograptus*, *Diplograptus*, *Ichthyograptus*, *Tetragraptus*, *Phyllograptus*, and *Cladograptus*), *Leptæna brevis*, traces of annelids, a few trilobites (*Strophomena*, *Asaphus*, &c.), some phylloporids (*Caryoceras*), and remains of plants (*Balnforthia*, &c.). In many places the slates have been metamorphosed, passing into chlorite-slate, mica-schist, and talc-schist, &c.,

with protrusions of granite, syenite, and other crystalline rocks. Towards the close of the long period represented by the Skiddaw slates, volcanic action manifested itself, first by intermittent showers of ashes and streams of lava which were interstratified with the ordinary marine sediment, and then by a more powerful and continuous series of explosions, whereby a huge volcanic mountain or group of cones was piled up above the sea-level. The length of time occupied by this volcanic episode in Cambrian geology may be inferred from the fact that all the Llandello and nearly all the Bala beds are absent here. The volcanic island slowly sank into a sea where Bala organisms flourished. Among these we find such familiar Bala species as *Favosites fibrosa*, *Helicolites interstinctus*, *Cypholeptus variicornis*, *Leptæna sericea*, *Orthos Actæonia*, *O. bifurcata*, *O. calligramma*, *O. elegantula*, *O. porcata*, and *Strophomena rhomboidalis*. These organisms and their associates gathered on the submerged flanks of the sinking volcano into a bed of limestone—the Coniston limestone—which can still be traced for many miles through the Westmoreland hills, as the Bala limestone which it represents can be followed through the volcanic tracts of North Wales. The Coniston limestone is covered by certain flags and grits which form their organic remains are referred to the Upper Silurian series.

In the South of Scotland, according to the detailed researches of the Geological Survey, the Lower Silurian formations are represented by the subjoined groups of strata in descending order—

Sandstones and conglomerates, Givran valley	} Llandoverly
Conglomerates, grits, shales, and lenticular bands of limestone, Peeblesshire, Dumfriesshire, S W Ayrshire, sometimes 2000 ft	
Carsphairn group, coarse pebbly grits and greywacke, 1200 ft	} Canadoc or Bala.
Upper Black Shale, with graptolites, 550 ft	
Lowther group, olive, grey, and blue shales, and sandstones, 4000 ft	} Llandello (14 000 ft)
Dalveen group, greywacke and shale, with band of fine conglomerate, 8500 ft	
Queensberry group, massive greywackes and grits, with occasional conglomerate bands and some shales, 4500 ft	
Lower or Moffat Black Shale group, 200–400 ft	
Ardwell group, brown flags, greywackes, and shales, sometimes purplish and red, base not seen	

As a whole these strata are singularly barren of organic remains. Most of the fossils which the Llandello groups contain lie in the bands of dark anthracite shale which have been traced across nearly the whole breadth of the country. These shales are covered with graptolites of recognizable Llandello forms, *Climacograptus teretiusculus*, *Diplograptus pristis*, and *Graptolites sagittarius* being particularly abundant. Crustacea are exceedingly rare, but two phyllopods, *Discoecia* is *Bromadia* and *Peltochasma apyphodes*, occur, while from Dumfriesshire two obscure trilobites are referred doubtfully to *Eoerinnurus* and *Phacops*. The vast thickness of sandy, gritty, and shaly unfossiliferous strata is the distinguishing feature of the Lower Silurian series in the south of Scotland. The Canadoc or Bala group lies unconformably upon the upper parts of the Llandello rocks. It contains in the eastern districts some calcareous conglomerates which here and there swell out into local masses of limestone. In the south-west of Ayrshire the limestones attain considerable dimensions. In these calcareous bands numerous Canadoc species have been found, among them *Chervurus gelatinosus*, *Eoerinnurus punctatus*, with species of *Mlenius* and *Asaphus*, *Orthos calligramma*, *O. confusus*, *Leptæna sericea*, *Maclurea*, and such corals as *Heliolites*, *Favosites*, *Diphygmia*, and *Stereophylla*. In the south-west of Ayrshire certain shales and sandstones full of Canadoc fossils are overlaid with sandstones, shales, and conglomerates containing *Pentamerus oblongus*, *Atrypa hemispherica*, *Meristella antiquifrons*, *Lichas lacunosa*, *Petraca elongata*, *Nidulites foveus*, and numerous other fossils which indicate the horizon of the Llandoverly rocks.

The Highlands of Scotland consist mainly of crystalline rocks—gneiss, mica-schist, chlorite-schist, clay-slate, quartz-rock, schistose flagstone, and many others, often much invaded by granite and other intrusive masses. It was at one time supposed that these rocks all belonged to the so-called primary or primitive series, older than any of the fossiliferous systems. But the discovery by Mr. C. W. Peach, already referred to, that recognizable fossils occur in the limestone of Durness in Sutherlandshire, led Murchison to infer that the whole of the overlying gneissose and schistose masses are really metamorphosed Lower Silurian rocks—a generalization which has been completely confirmed by subsequent investigation. At

the base of this great series of rocks masses of white quartz rock are found lying with a marked unconformability upon the red sandstones described in a previous page. These quartzose beds are merely hardened and somewhat metamorphosed sandstones; they still show their original false-bedding, and the casts of sea-weeds and worm-burrows. They contain a band of limestone which in Assynt swells out to a thickness of 1000 feet or more, and can be traced almost continuously from the Kyles of Skye to the north coast of Sutherlandshire. Over these strata, in perfect conformable sequence, and with a complete lithological gradation, come quartzose flagstones dipping like the rocks below at gentle angles to the south-east. They become more schistose and crumpled as they are traced upwards, until, after a thickness of several thousand feet has been passed over, they begin to undulate in steep folds and pass into the ordinary schistose rocks which cover so much of the Highlands. The gradation from the compactly unaltered lower quartz-rocks and limestones on the west to the intensely crumpled crystalline upper schists and flagstones on the east can be followed step by step in numerous fine natural sections from the north of Sutherland to the Kyles of Skye. The proof is thus complete that a vast mass of schists and other crystalline rocks overlies fossiliferous limestones in the Scottish Highlands. It therefore becomes of the utmost importance to determine the geological horizon of the fossils in the limestones. This was done by the late Mr. Salter, who declined his contention that they were unequivocally Lower Silurian, and bore a most remarkable resemblance to a group of fossils from the Lower Silurian rocks of North America. Five of the species he regarded as identical with known American forms (*Orthoceras aciculatum*, Hall, *Orthos strobilata*, Emmons, *Ophileta compacta*, Salt, *Myriochasma gracilis*, Hall; *Al. bellinensis*, Hall), 4 as representative, 3 doubtful, and 1 new genus, found also in Canada. "That this truly North American assemblage," he remarks, "should be found in the extreme north of Scotland on the same parallel as the Canadian,—that species of *Maclurea* and *Diphygmia*, resembling those of the St. Lawrence basin, and *Orthoceras*, bearing large affinities like those of North America, Scandinavia, and Russia, should occur in Scotland and yet be scarcely known far the south, is at least suggestive of a geographical distribution—perhaps even of climatal conditions—not very unlike that of more modern times." From this paleontological decision it follows that the overlying schistose series of the Scottish Highlands is a mass of metamorphosed Silurian strata. Examined in detail they show very unequal and sporadic metamorphism. Some portions are scarcely more changed than the others, and the same is the case of unaltered districts. False-bedding, pebble-beds, and other common features of sedimentation occur abundantly throughout the whole vast series of schists. Here and there the metamorphism has become extreme, the rocks passing into coarsely crystalline schists full of garnets, with bands of hornblende-rock, actinolite-schist, and other metamorphic products, and passing even into gigantic gneiss and true granite. No more convincing proof could be obtained that vast masses of schist do not necessarily belong to an ætate period of the earth's history, but may have been produced by the alteration of previously existing sediments.

It is not necessary to believe that the sediments so altered were in all cases more ordinary marine sand and mud. The white quartz-rocks were no doubt at one time pure white siliceous sand, the rounded grains of which can still be readily detected in them. The quartzose flagstones were stratified sand with thin partings of clay or mud. The clay slates were evidently thick accumulations of mud. But the rocks containing a large variety of schistose gneiss, such as chlorite-schist, actinolite-schist, hornblende-rock, &c., may have resulted from the alteration of volcanic sediments and submarine lavas. The evidence from Cumberland and Wales proves how voluminous and long continued were the volcanic eruptions of the Lower Silurian period in Britain. The abundant diffusion of volcanic detritus over the present sea-bottom is now well known. The "Challenger" researches have also shown us that, besides the glauconite previously known to be deposited from sea-water in the chambers of foraminifera and other dead organisms on the ocean-bottom, true magnesian silicates are now in the process of elimination from sea-water in some of the abysses of the ocean. It is quite possible therefore that some of the rocks of the metamorphic series rich in magnesian silicates may have arisen from the alteration of volcanic tuffs or submarine lavas, and that others may owe their distinctive composition to original chemical precipitation, as ably contended by Sterry Hunt, though their present crystalline structure must be regarded as a part of the general metamorphism by which the whole of the Lower Silurian rocks of the Highlands have been affected.

In the south-east of Ireland, grey, greenish, and purple grits, and grey and dark shales, lie unconformably upon the Cambrian rocks, and contain a few fossils of Llandello age. They present unstratified beds of tuff and felsitic lavas indicating contemporaneous volcanic action. In the north-east of the island a broad

belt of Lower Silurian rocks runs from the coast of Down into the heart of Roscommon and Longford. This belt is evidently a prolongation of that in the southern uplands of Scotland. It is marked by the occurrence of sandal dala anthracitic shales crowded with grayolites. The richest fossiliferous localities among the Irish Lower Silurian rocks are found at the Chair of Kildare, Portrane near Dublin, Pountney in Tyrone, and Lissellan in Fermanagh, where small portions of the older rocks rise as oases among the surrounding lava formations. Portlock brought the northern and western localities to light, and Macpherson pointed out that, while a number of the trilobites (*T. nuda*, *Phacops*, *Calyptene*, and *Atrypa*), as well as the simple plated *Otholites*, *Leptæna*, and *Strophomena*, some spiral shells, and many *Othoceras*, are specifically identical with those from the typical Caradoc and Bala beds of Shropshire and Wales, yet they are associated with peculiar forms, first discovered in Ireland, and very rare elsewhere in the British Islands. Among these distinctive fossils he cites the trilobites, *Isenopora* *ides*, *Harpes*, *Amphioxys*, and *Dendrodes*, with the smooth forms of *Asaphus* (*Sodestus*), which, though abundant in Ireland and America, seldom occur in Wales or England, and never on the Continent.¹

In the north and west of Ireland a large area of surface is occupied by crystalline rocks—gneiss, schists, quartz rocks, limestone, granite, &c.—which are manifestly a continuation of those of the Highlands of Scotland. They run south-westward parallel with the belt of unaltered Lower Silurian rocks from which, in some places, as in county Tyrone, they are only a few miles distant. The district of Fomeroy, so rich in Silurian fossils, promises to afford the greatest light on the interesting but difficult problem of the metamorphism of the Lower Silurian rocks of the Scottish Highlands and the north-west of Ireland. It will be seen from the evidence furnished by the sections in West Mayo (p. 337) that the metamorphism must have taken place prior to the deposition of the Upper Silurian formations of the west of Ireland.

B. Upper Silurian.

The formations which in the British Islands are classed as Upper Silurian occur in two very distinct types. So great indeed is the contrast between these types that it is only by a comparison of organic remains that the whole can be grouped together as the deposits of one great geological period. In the original region described by Murchison, and from which his type of the system was taken, the strata are comparatively flat, soft, unaltered, consisting mainly of somewhat meagre sandy mud with occasional bands of limestone. But as these rocks are followed into North Wales, they are found to swell out into a vast series of grits and shales so like portions of the hard altered Lower Silurian rocks that, save for the evidence of fossils, they would naturally be grouped as part of that more ancient series. In Westmoreland and Cumberland, and still further north in the border counties of Scotland, and also in the south-west of Ireland, it is the North Welsh type which prevails, so that in Britain the general lithological characters and minute paleontological subdivisions ascertained in the typical Silurian district are almost confined to that limited region, while over the rest of the British area for thousands of square miles the hard sandy and shaly type of North Wales is prevalent.

Taking first the Silurian tract of the south-west of England, and the east and south of Wales, we find a decided unconformability separating the Lower from the Upper Silurian formations. In some places the latter are found passing across the edges of the former, group after group, till they come to lie directly upon the Cambrian rocks. Indeed, in one district between the Longmynd and Wenlock edge, the base of the Upper Silurian rocks is found within a few miles to pass from the Caradoc group across to the Lower Cambrian rocks. It is evident, therefore, that in the Welsh region very great disturbance and extensive denudation preceded the commencement of the deposition of the Upper Silurian rocks. As Professor Ramsay has pointed out, the area of Wales, previously covered by a wide though shallow sea, was ridged up into a series of islands, round the margin of which the conglomerates at the base of the Upper

Silurian series began to be laid down. This took place during a time of submergence, for these conglomeratic and sandy strata are found creeping up the slopes and even capping some of the heights, as at Bognmire, where they reach a height of 1150 feet above the sea.² The subsidence probably continued during the whole of the interval occupied by the deposition of the Upper Silurian strata, which thus were piled to a depth of from 2000 to 5000 feet over the disturbed and denuded platform of Lower Silurian rocks.

Arranged in tabular form, the subdivisions of the Upper Silurian rocks of Wales and the adjoining counties of England are in descending order as follows:—

		Base of Old Red Sandstone Trilobites
3	Ludlow group	Upper Ludlow Rock Atrypine Limestone Lower Ludlow Rock
2	Wenlock group	Wenlock or Dudley Limestone Wenlock Shale Woolhope or Dair Limestone and Shale
1.	Upper Llandovery group	Taunton Shale May Hill Sandstones Lower Llandovery Rocks

{ Denbighshire
Grits of
North Wales

1. Upper Llandovery Group.—(a.) May Hill Sandstones.

—The position of these rocks as the true base of the Upper Silurian formations was first shown in 1853 by Sedgwick, who named them the May Hill Sandstones from the locality in Gloucestershire where they are so well displayed. Appearing on the coast of Pembroke-shire at Malpas Bay, they range across South Wales until they are overlapped by the Old Red Sandstone. They emerge again in Carmarthenshire, and trend north-eastward as a narrow strip at the base of the Upper Silurian series, from a few feet to 1000 feet or more in thickness, as far as the Longmynd, where as a marked conglomeratic wrapping round that ancient Cambrian ridge they disappear. In the course of this long tract they pass successively and unconformably over Lower Llandovery, Caradoc, Llandeleio, and Cambrian rocks. They consist of yellow and brown ferruginous sandstones, often full of shells, which are apt to weather out and leave casts. Their lower parts are commonly conglomeratic, the pebbles being largely derived from older parts of the Silurian formations. Here and there, where the organic remains become extraordinarily abundant, the strata pass into a kind of sandy limestone, known as the "Pentamerus limestone," from the numbers of this brachiopod contained in it. The species of fossils found in the May Hill Sandstones number about 230.

Among these are some traces of bryozoa, sponges (*Cliona*, *Ischadites*); the widely diffused *Gryptolites prionus*, a number of corals (*Pachydictya*, *Hierulites*, *Favosites*, *Ortholites*, *Synaptolites*, &c.), a few corals; some annelids, particularly the *Tentaculites* annulus, which is abundant, a number of trilobites, of which *Phacops Stokesi*, *P. vancouveri*, *Enerthis punctatus*, and *Calyptene Dilettabachii* are common; numerous brachiopods, as *Atrypa hemisphaerica*, *A. reclusiana*, *Pentamerus oblongus*, *Strophodonta liratus* (8 tentacles also occurs), *Leptæna transversalis*, *Ortholites calligynus*, *O. elongatus*, *O. reversa*, *Strophomena compressa*, *S. pecten*, and *Lingula parallela*; lamellibranchs of the mytiloid genera *Orthis*, *Atrypa*, and *Modiolopsis*, with forms of *Merina*, *Clanadonia*, and *Lyrodesma*; gastropods, particularly the genera *Murchisonia*, *Pleurotomaria*, *Cyclonema*, *Holopora*; and cephalopods, chiefly *Orthoceras*, with some forms of *Actinoceras* and *Phragmoceras*, and the old species *Litulus cornu-arvæ*.

(b.) *Purannon Shale*.—Above the Upper Llandovery beds comes a very persistent zone of fine, smooth, light grey or blue slates, which has been traced down the whole length of Wales from the mouth of the Conway into Carmarthenshire. These rocks, termed the "paste-rock" by Sedgwick, have an extreme thickness of 1000 to 1500 feet. Barren in organic remains, their chief interest lies in the fact that

¹ *Siluria*, p. 174.

² *Physical Geology of Britain*, p. 91.

the persistence of so thick a band of rock between what were supposed to be continuous and conformable formations should have been unrecognized until it was proved by the detailed mapping of the Geological Survey.

2 *Wenlock Group*.—(a) *Woolhope Limestone*.—In the original typical Upper Silurian tract of Shropshire and the adjacent counties, the Upper Llandovery rocks are overlaid by a local group of grey shales containing nodular limestone which here and there swells out into beds having an aggregate thickness of 30 or 40 feet. These strata are well displayed in the picturesque valley of Woolhope in Herefordshire, which lies upon a worn quaquaversal dome of Upper Silurian strata rising in the midst of the surrounding Old Red Sandstone. They are seen likewise to the northwest at Presteign, Nash Scar, and Old Radnor in Radnorshire, and to the east and south in the Malvern Hills (where they include a great thickness of shale below the limestone), and May Hill in Gloucestershire. These strata have yielded many characteristically Upper Silurian fossils, among which may be mentioned *Dumastus Butiensis*, *Homalonotus delphinoccephalus*, *Phacops caudatus*, *Atrypa reticularis*, *Orthis calligramma*, *Strophomena umbra*, *Rhynchonella boealis*, *R. Wilsoni*, *Eumorphus sculptus*, *Orthoceras annulatum*.

It is a characteristic of the older Paleozoic limestones to occur in a very lenticular form, swelling in some places to a great thickness and rapidly dying out, to reappear again perhaps some miles away with increased proportions. This local character is well exhibited by the Woolhope limestone. Where it dies out, the shales underneath and intercalated with it join on continuously to the overlying Wenlock shale, and no line for the Woolhope group can then be satisfactorily drawn. The same discontinuity is strikingly traceable in the Wenlock limestone to be immediately referred to.

(b) *Wenlock Shale*.—This is a group of grey and black fine shales, traceable from the banks of the Severn near Coalbrook Dale across Radnorshire to near Carmarthen—a distance of about 90 miles. The same strata reappear in the protrusions of Upper Silurian rock which rise out of the Old Red Sandstone plains of Gloucestershire, Herefordshire, and Monmouthshire. In the Malvern Hills they were estimated by Professor Phillips to reach a thickness of 640 feet, but towards the north they thicken out to 1000 or even 1400 feet. On the whole the fossils are identical with those of the overlying limestone. The corals, however, so abundant in that rock are here comparatively rare. The brachiopods (of the genera *Leptæna*, *Orthis*, *Strophomena*, *Atrypa*, and *Rhynchonella*) are generally of small size—*Orthis biloba*, *O. hybrida*, and the large flat *O. rustica*, being characteristic. Of the higher mollusca thin-shelled forms of *Orthoceras* are especially abundant. Among the trilobites, *Encrinurus punctatus*, *E. variolarius*, *Calymene Blumenbachii*, *C. tuberculosa*, *Phacops caudatus*, and *P. longicaudatus* are common. The *Graptolithus pridianus*, so frequent among the Bala beds of the Lower Silurian series, also occurs in the Wenlock shale. *Graptolithus Flemmingi* is here a characteristic species.

(c) *Wenlock Limestone* is a thick-bedded, sometimes flaggy, usually more or less concretionary limestone, grey or pale pink, often highly crystalline, occurring in some places as a single massive bed, in others as two or more strata separated by grey shales, the whole forming a thickness of rock ranging from 100 to 300 feet. As its name denotes, this stratum is typically developed along Wenlock Edge in Shropshire, where it runs as a prominent ridge for fully 20 miles, also between Aymestry and Ludlow. It likewise appears at the detached areas of Upper Silurian strata above referred to, being specially well seen near Dudley (whence it is often spoken of as the Dudley limestone), Woolhope, Malvern, May Hill, and Usk in Monmouthshire.

A distinguishing characteristic of the Wenlock limestone is the abundance and variety of its corals, of which 53 species have been described. The rock seems indeed to have been formed in part by massive sheets and bunches of coral. Among characteristic species are *Heliolites calcareus*, *Heliolites interstinctus*, *H. tubulatus*, *Alveolites Lubachi*, *Furcata wrighti*, *F. fibrosa*, *F. Gothlandica*, *Cerates juniperensis*, *Syringopora fusciculatus*, and *Omphypora tubuliformis*. The crinoids are also specially abundant, and are often beautifully preserved. *Teuthoceras moniliformis* is one of the most frequent species, others are *Ophiletes rugosus*, *Cyathocrinus goniatoides*, and *Mastigocrinus celatus*, with several cystideans, as *Pseudocrinus quadrifidus* &c. The crustaceans include numerous trilobites, among which we miss some of the persistent Lower Silurian genera, such as *Asaphus*, *Ogygia*, and *Triaclonus*, none of which ascend into the Wenlock group. The most abundant trilobite is the long-lived *Calymene Blumenbachii*, which ranges from the Llandovery flag up to near the top of the Upper Silurian formations. It occurs abundantly at Dudley, where it received the name of the "Dudley Locomotive." Other common forms are *Encrinurus punctatus*, *E. variolarius*, *Phacops caudatus*, *P. Douvillei*, *P. Stoliczka*, *Dumastus Butiensis*, *Homalonotus delphinoccephalus*, and *Cheurus bisinuatus*. The brachiopods continue to be abundant, among typical species may be noted *Atrypa reticularis*, *Moschellium lamella*, *Spizyer clavatus*, *S. plicatulus*, *Rhynchonella boealis* (very common), *R. cuneata*, *R. Wilsoni*, *Orthis elegantula*, *O. rustica*, *Strophomena rhomboidalis*, and *Pentamerus planus*. The lamellibranchs are not well represented, but several species of *Pternarca* are abundant, with *Goniatites angulata*, and some species of *Molodops* and *Cycloneta*. The gastropods are most characteristically marked by 8 or 9 species of *Eumorphus*, 3 or more of *Murchisonia*, with species of *Pleuromma*, *Acoculla*, and *Cyclonema*. The cephalopods are confined to few genera, *Lutites*, *Aduncoceras*, *Cyrtoceras*, *Orthoceras*, and *Pteronoceras*, of these the orthoceratites are by far the most abundant both in species and individuals. *Orthoceras annulatum* is the most common form. The pteropods appear in the Wenlock and very abundant *Conularia Soucchi*, and the heteropods in the common and characteristic *Bellerophon Wenlockensis*.

3. *Ludlow Group*.—This series of strata consists essentially of shales, with occasionally a calcareous band in the middle. It graduates downward into the Wenlock group, so that when the Wenlock limestone disappears the Wenlock and Ludlow shales form one continuous argillaceous formation. It is in this united form that the two groups stretch to the south-west through Brecon and Carmarthen. The Ludlow rocks are typically seen between Ludlow and Aymestry. They appear likewise at the detached Silurian areas from Dudley to the mouth of the Severn. They were grouped by Murchison into three zones.

(a) *Lower Ludlow Rock*.—This is a group of soft dark-grey to pale greenish-brown or olive sandy shales, often with calcareous concretions. Much of the rock, however, presents so little fissile structure as to get the name of mudstone, weathering out into concretions which fall to angular fragments as the rock crumbles down. It becomes more sandy and flaggy towards the top. From the softness of the shales this zone of rock has been extensively denuded, and the Wenlock limestone rises up boldly from under it.

An abundant suite of fossils has been yielded by these shales. No fewer than 18 species of star-fishes, belonging to 6 genera, have been described (*Prolatera*, like the brittle-stars of the British seas, *Palæosoma*, *Palæosternia*). A few graptolites occur, particularly the persistent *Graptolithus pridianus* (common), *G. colous*, and *G. Flemings*. A few of the Wenlock corals survive in the Lower Ludlow rock, but the conditions of deposit were evidently unfavourable for their growth. The trilobites are less numerous than in older beds; they include the venerable *Calymene Blumenbachii*, *Phacops caudatus*, and its still longer-lived variety *P. longicaudatus*, also *Acidaspis Dringhi*, *Homalonotus delphinoccephalus*, and *Cyphaspis megalops*. But other forms of crustacean life occur in some number. As the trilobites began to wane numerous phylloporids appear, the genus *Cephrocypris* being represented by 10 or more species. Large eurypterids now make their entrance upon geological history—*Eurypterus*, *Pterygotus*, and *Hemipterus*. Though brachiopods are not scarce, hardly any seem to be peculiar to the Lower Ludlow rock, the *Longula lata*, which Murchison suggested might be peculiar, having been obtained from what is supposed to be representative of this group of strata in Westmoreland. *Rhynchonella Wilsoni*, *Spizyer caperatus*, *Strophomena euglypha*, *Atrypa reticularis*, and *Chonetes murina* are not infre-

quent. Among the more frequently recurring species of lamellibranchs the following may be named—*Gastrolia interrupta*, *G. strata*, *O. thouda rugata*, *O. senaria*, and a number of species of *Pterinea*. The orthoconites are numerous, as *O. thoeves Ludlowi*, *O. subundulatum*, also species of *Phragmoceras* and *Laticeras*. The numbers of these straight and curved cephalopods form one of the distinguishing features of the zone. At one locality, near Leutwaine in Shropshire, which has been prolific in Lower Ludlow fossils, particularly in star-fishes and eurypterid crustaceans, a fragment of the fish *P. agius* was discovered in 1859. This is the earliest trace of vertebrate life yet detected. It is interesting to note that the *Pteropodus* does not stand low in the scale of organization, but has affinities with our modern slug-stomach.

(b) *Aymestry Limestone* is a dark grey somewhat earthy concretionary limestone in beds from 1 to 5 feet thick. Where at its thickest it forms a conspicuous feature, rising above the soft and denuded Lower Ludlow shales and, owing to the easily removable nature of some fuller's earth on which it lies, it has here and there been dislocated by large landslips. It is still more inconstant than the Wenlock limestones. Though well developed at Aymestry it soon dies away into bands of calcareous nodules, which finally disappear, and the lower and upper divisions of the Ludlow group then come together. The most characteristic fossil is the *Pentamerus Knighti*, other common forms are *Rhynchonella Wilsoni*, *Lingula Lewisii*, *Strophomena euglypha*, *Bellerophon dilatatus*, *Pterinea Sowerbyi*, with many of the same shells, corals, and trilobites found in the Wenlock limestone. Indeed, as Murchison has pointed out, except in the less number of species and the occurrence of some of the shells more characteristic of the Upper Ludlow zone, there is not much paleontological distinction between the two limestones.¹

(c) *Upper Ludlow Rock*.—In the original Silurian district described by Murchison, the Aymestry limestone is covered by a calcareous shelly band full of *Rhynchonella navicula*, sometimes 30 or 40 feet thick. This layer is succeeded by grey sandy shale or mudstone, often weathering into concretions, as in the Lower Ludlow zone, and assuming externally the same rusty-brown or greyish olive-green hue. Its harder beds are quarried for building stone, but the general character of the deposit, like that of the argillaceous portions of the Upper Silurian formations as a whole in the typical district of Siluria, is soft, incoherent, and crumbling, easily decomposing once more into the original mud, and presenting in this respect a contrast to the hard fissile and often slaty shales of the Lower Silurian series. Many of the sandstone beds are crowded with ripple-marks, rill-marks, and annelid-trails, indicative of the shallow littoral waters in which they were deposited. One of the uppermost sandstones is termed the "Fucoid Bed" from the number of its cylindrical sea-weed-like stems. It likewise contains numerous inverted pyramidal bodies, which are believed to be casts of the cavities made in the muddy sand by the rotatory movement of crinoids rooted and half-buried in the micaceous mud.² At the top of the Upper Ludlow rock near the town of Ludlow, a brown layer occurs from a quarter of an inch to 3 or 4 inches in thickness, full of fragments of fish, *Pterygodus*, and shells. This layer, termed the "Ludlow Bone-bed," is the oldest from which any considerable number of vertebrate remains has been obtained. In spite of its insignificant thickness it has been detected at numerous localities from Ludlow as far as Pytton passage, at the mouth of the Severn—a distance of 45 miles from north to south, and from Kingston to Ledbury and Malvern—a distance of nearly 30 miles from west to east; so that it probably covers an area (now largely buried under Old Red Sandstone) not less than 1000 square miles in extent, yet it appears never to exceed and usually to fall short of a thickness of 1 foot. Fish remains, however, are not confined to this horizon. They have been detected in

strata above the original bone-bed at Ludlow, together with some minute globular bodies believed to be the sporangia of a lycopod. These, with some other plant remains from the same district, are the earliest traces of land vegetation yet found. The higher parts of the Ludlow rock consist of fine yellow sandstone and harder grits known as the Downton sandstone. Originally the whole of these flaggy upper parts of the Ludlow group were called "Thlestones" by Murchison, and being often red in colour were included by him as the base of the Old Red Sandstone, into which they gradually and conformably ascend. Undoubtedly they show the gradual change of physical conditions which took place at the close of the Silurian period in the west of England, and brought in the deposits of the Old Red Sandstone. But as their organic contents are still unequivocally those of the Ludlow group, they are now classed as the uppermost zone of the Silurian system.

A considerable suite of organic remains has been obtained from the Upper Ludlow rock, which on the whole are the same as those in the zones underneath. Vegetable remains, some of which seem to be lycopods, but most of which are probably terrestrial and lycoperidaceous, abound in the Downton sandstone and passage-beds into the Old Red Sandstone. Conifers, as might be supposed from the muddy character of the deposit, seldom occur, though Murchison mentions that the encrusting form *Alveolites fibrosus* may not infrequently be found enveloping shells, *Cyclonema corallii* and *Murchisonia corallii* being, as their names imply, its favourite habitats. Some annelids (*Scaphites longispinus*, *Comolites sepulchralis*, *Tentaculites tenuis*, and *Triachylepteria coruacea*) are not uncommon. The crustacea are represented chiefly by small ostracods (*Pteropoda Kioelini*, *Lepidocaris puerilis*, *Ensis tuberosa*), and by species of *Ceraticaris*, *Dicellocaris*, *Eurypterus*, *Henneguya*, *Pterygodus*, and *Stylonurus*, the trilobites having still further waned, though *Hemalonotus Knighti*, *Ebenurus minutus*, *Phacops Downeyi*, and a few others still occur, and even the persistent *Calymene Dibunabachi* may occasionally be found. Of the brachiopods the most abundant forms are *Rhynchonella navicula*, *Goniatites stictella*, *Dicaria rugata*, and *Lingula cornuta*. The most characteristic lamellibranchs are *Orthis rugulata*, *Gonophora euglypha*, *Pterinea lineata*, *P. retroflecta*, some of the commonest gastro-pods are *Murchisonia corallii*, *Platyschisma helveticum*, and *Isopodella obsoleta*. The orthoconites are specifically identical with those of the Lower Ludlow rock, and are sometimes of large size, *Orthoceras bullatum* being specially abundant. The fish remains consist of bones, teeth, shagreen-like scales, plates, and fin-spines. They include some plagiostomous (placoid) forms (*Thelodus*, shagreened scales, *Sphagodus*, skin, *Onchus*, spines) and some osteocosteous (*Cephalaspis*, *Auchenaspis*, and *Pteraspis*).

In the typical Silurian region of Shropshire and the adjacent counties, nothing can be more decided than the lithological evidence for the gradual disappearance of the Silurian sea, with its crowds of graptolites, trilobites, and brachiopods, and for the gradual introduction of those geographical conditions which brought about the deposit of the Old Red Sandstone. The fine grey and olive-coloured muds, with their occasional zones of limestone, are succeeded by bright red clays, sandstones, concretionstones, and conglomerates. The evidence from fossils is equally explicit. Up to the top of the Ludlow rocks the abundant Silurian fauna continues in hardly diminished numbers. But as soon as the red strata begin the organic remains rapidly die out, until at last only the fish and the large eurypterid crustaceans continue to occur.

Turning now from the interesting and extremely important though limited area in which the original type of the Upper Silurian rocks is developed, we observe that whether we pass northwards or south-westwards the soft mudstones and thick limestones give way to hard slates, grits, and flagstones, among which it is scarcely possible sometimes even to discriminate what represents the Wenlock from what may be the equivalent of the Ludlow group. It is in Denbighshire and the adjacent counties that this change becomes most marked. The Tarannon shale above described passes into that region of North Wales, where it forms the base of the Upper Silurian formations. It is covered

¹ Siluria, p. 130.² Siluria, p. 133.

by a series of grits or sandstones which in some places are at least 3000 feet thick. These are covered by and pass laterally into hard shales, which are believed to represent parts of the true Wenlock group, perhaps even some portion of the Ludlow rocks. It is evident, however, that in spite of the wide extent over which these Silurian rocks of North Wales are spread, and the great thickness which they attain, they do not present an adequate stratigraphical equivalent for the complete succession in the original Silurian district. Instead of passing up conformably into the base of the Old Red Sandstone, as at Ludlow, they are covered by that formation unconformably. In fact they have been upturned, crumpled, faulted, and cleaved before the deposition of those portions of the Old Red Sandstone which lie upon them. These great physical changes took place in Denbighshire when, so far as the evidence goes, there was entire quiescence in the Shropshire district; yet the distance between the two areas was not more than about 60 miles. These subterranean movements were doubtless the precursors of those more widely extended upheavals which converted the floor of the Silurian sea into a series of isolated basins, in which the Old Red Sandstone was laid down.

In Westmoreland and Cumberland a vast mass of hard slates, grits, and flags was identified by Sedgwick as of Upper Silurian age. These form the varied ranges of hills in the southern part of the lake district from near Shap to Duddon mouth. The following are the local subdivisions with the conjectural equivalents in Siluria.¹

Hay Fell and Kixby Moot Flags	Flaggy beds, with lamellibranchs abundant	= (?) Tilestones
	Massive greenish and grey sandstones, with bands of fossils, <i>Holoptella</i> abundant	
Bunnsdale Slates	Calcareous beds, with <i>Rhynchonella navicula</i> abundant	= } Aymestry Limestone
	Sandstone and shale, with staurolite	
	Dark blue flags and grits of great thickness	= } Upper Wenlock.
Coulston Grits	Flags and greywacke (<i>Orthoceras subundulatum</i> , <i>O. angulatum</i> , <i>Graptolithus Flemingii</i> , <i>G. colonus</i> , <i>Ceratoceras Murchisoni</i>), upwards of 4000 feet	= } Lower Wenlock.
	Dark grey coarse flags (<i>Candolite undulata</i> , <i>Orthoceras subundulatum</i>), 1000 feet	
Coulston Limestone (Lower Silurian)		= } Caradoc or Bala.

In the northern part of the Lake district a great anticlinal fold takes place. The Skiddaw slates arch over and are succeeded by the base of the volcanic series above described. But before more than a small portion of that series has appeared the whole Silurian area is overlapped unconformably by the Carboniferous Limestone series. It is necessary to cross the broad plains of Cumberland and the south of Dumfriesshire before Silurian rocks are again met with. In this intervening tract a synclinal fold must lie, for along the southern base of the uplands of the south of Scotland a belt of Upper Silurian rocks, dipping on the whole to the south-east, can be traced from the heart of the Cheviot Hills to the headlands of Wigtonshire. These rocks must reach a thickness of several thousand feet, but their top is nowhere seen. They repose on some of the older parts of the Llandello series, with so close a coincidence of dip and strike that no decided unconformability has yet been traced between them. They consist essentially of shales, with a

considerable proportion of greywacke bands towards the base. At different horizons they contain lenticular bands of a calcareous pebbly grit. But their most characteristic feature, and one which at once distinguishes them locally from the adjoining Lower Silurian rocks, is the occurrence of a nearly black, highly fissile shale, composed of layers in most cases as thin as ordinary writing paper and usually crowded with graptolites. These peculiar bands occur throughout the whole series of rocks from bottom to top. They are sometimes so thin that 20 or 30 seams or ribs, each finely fissile, may be seen intercalated within the space of an inch of the ordinary shale or greywacke. Occasionally they form zones 80 to 100 feet thick, consisting entirely of finely leaved graptolitic shales. As a whole these Upper Silurian strata resemble lithologically the corresponding series in Westmoreland, though here and there they assume the character of mudstones not unlike those of Shropshire. The abundant fossils in them are simple graptolites (*Graptolithus Sedgwicki*, *G. Becki*, *G. Flemingii*, *G. colonus*, *G. Græstonensis*, *Retiolites Geinitzius*, &c.). *Orthoceras* comes next in point of numbers (*Orthoceras annulatum*, *O. tenuicinctum*, &c.). In some of the shales crustacean fragments are numerous. They include large pieces of the carapace of *Dictyocaris*, with remains of *Pterygotus* and *Ceratocaris*. The pebbly grits contain *Petraria* and crinoid stems. In the south of Kirkcudbright certain limestones and conglomerates intercalated among these shales have yielded a more varied fauna, having on the whole a decidedly Wenlock character. It includes *Favosites*, *Catenipora*, *Beyrichia tuberculata*, *Phacops caudatus*, *Meistella*, *Leptæna sericea*, *Atrypa reticularis*, *Strophomena imbrex*, *Murchisonia*, *Orthoceras tenuicinctum*, &c.

It is impossible in the south of Scotland to separate the Upper Silurian rocks into Wenlock and Ludlow groups. On the whole these rocks seem to be representative mainly of the older half of the Upper Silurian formations. They are covered unconformably by Lower Old Red Sandstone and later formations. In the counties of Edinburgh and Lanark, however, the base of the Lower Old Red Sandstone is found to graduate downward into a thick series of brown, olive, and grey shales, sandstones, and grits, containing undoubted Ludlow fossils. It is deserving of remark also that the peculiar lithological type so characteristic of the strata in the original Silurian area reappears in the centre of Scotland, many of the concretionary brown shales and olive-coloured mudstones being undistinguishable from those in the typical sections at Ludlow. Some of these beds are crowded with fossils. Among the most characteristic are *Leptæna transversalis*, *Orthoidea amgdalata*, *Platyschisma helveticæ*, *Beyrichia Klodeni*, *Orthoceras Maclarenii*, with many crustaceans of the genera *Ceratocaris*, *Eurypterus*, *Pterygotus*, *Stenomoma*, and *Stylonurus*. In the Pentland Hills these strata are estimated to attain a thickness of 3500 to 4000 feet, but their base is nowhere reached; in Lanarkshire they are at least as thick. Their lower portions may represent some of the higher parts of the Wenlock group.

Ireland furnishes some interesting evidence regarding the geographical changes in the west of Europe between the close of the Lower Silurian and the beginning of the Upper Silurian period. It has already been pointed out that the metamorphosed Lower Silurian rocks of the Scottish Highlands are prolonged into the north of Ireland, whence they range south-westwards to Galway Bay. In the picturesque tract between Loch Mask and the mouth of Killybeg harbour these metamorphosed rocks are unconformably overlaid by masses of sandstones, conglomerates, and shales more than 7000 feet thick, and containing Llandovery and Wenlock fossils with a mixture of Caradoc forms. In the midst

¹ The arrangement and thicknesses here given are those in the Kendal district as mapped by Mr Aveline and Mr Hughes in the course of the Geological Survey (*Sheet 98, S.E., Explanation*, pp. 6-13, 1872)

of the greatly metamorphosed Lower Silurian platform, portions are to be found still little altered and full of fossils. The overlying Upper Silurian strata have not been metamorphosed, but contain pebbles of the altered rocks on the upturned edges of which they lie. It is evident therefore, as Mr Hull has remarked, that the metamorphism must have occurred between the close of the Lower and the commencement of the Upper Silurian period.¹ In connexion with this question it should be remarked that abundant volcanic activity accompanied the deposit of these Upper Silurian rocks in the west of Ireland, successive sheets of lava (eurite) and beds of tuff forming conspicuous bands among the stratified rocks, and reaching a collective thickness of 800 feet and upwards. Between Brandon Head and Dingle Bay a thick mass of strata on the coast, must, from the comparatively few fossils obtained from it, be held to represent Upper Silurian formations.

CONTINENTAL EUROPE.—The broad hollow which, running from the mouth of the English Channel across the plains of northern Germany into the heart of Russia, divides the high grounds of the north and north-west of Europe from those of the centre and south, separates the European Silurian area into two distinct tracts. In the northern of these we find the Lower and Upper Silurian formations attaining an enormous development in Britain, but rapidly diminishing in thickness towards the north-east, until in the south of Scandinavia and the Gulf of Finland they reach only about $\frac{1}{10}$ th of that depth. In these tracts, too, they have on the whole escaped so well from the dislocations, crumplings, and metamorphisms so conspicuous to the south-west, that to this day they remain over wide areas nearly as horizontal and soft as at first. In the southern tract Silurian rocks appear only here and there from amidst later formations, and almost everywhere present proofs of intense subterranean movement.

In the south of Scandinavia (Christiana, Mysen See, Malmö, Gotland) the Lower and Upper Silurian rocks attain a united thickness of not more than about 1200 feet, yet are said to contain representatives of all the leading subdivisions of the British series. The following table exhibits the Silurian succession in the south of Norway and Sweden, with the supposed English equivalents:—

Sandy beds, with <i>Pterinea retroflexa</i> , <i>Rhynchonella suecica</i> , <i>Orthis retusa</i> , <i>Bellerophon tuberculata</i> S. Gotland	= Upper Ludlow
Upper Malmö limestone	
Upper Graptolite mals, with <i>Graptolithus gracilis</i> (Ludense) abundant	= Lower Ludlow.
Lower Malmö or upper Orthoceratite limestone, with large <i>Orthoceras</i> having conical apophyses	
Enerinitic schists with orthoceratites and <i>Goniatites pygmaeus</i>	
Coral limestone (<i>Goniatites turbulatus</i> and other Wenlock corals)	= Wenlock.
Pentamerus limestone, <i>Pentamerus oblongus</i> , <i>P. galatus</i> , <i>Stricklandina lens</i> , <i>Leptæna transversalis</i> , <i>Euchinus punctatus</i> , &c.	= Llandovery.
Lower argillaceous schists	
Calcareous sandstones (containing a mixture of Llandovery forms, as <i>Atristella angulifrons</i> , and many large smooth <i>Pentameri</i>)	
Calcareous and argillaceous flagstones, <i>Orthis calligramma</i> , <i>O. testudinaria</i> , <i>O. speciosa</i> , <i>Leptæna sericea</i> , <i>Goniatites quadrifidus</i> , <i>Atristella expansa</i> , <i>Trinacrus concentricus</i> , &c.	= Caradoc.
Orthoceratite limestone and lower Enerinitic schists	
Upper Graptolite schists, with <i>Diplograptus pristis</i> , <i>D. folium</i> , <i>D. levatusculus</i> , and forms of <i>Asaphus</i> , <i>Ogygia</i> , <i>Trinacrus</i> , &c.	
Lower Orthoceratite limestone, with <i>Orthoceras duplex</i> , <i>O. annulatum</i> , <i>Lobatus cornu-eris</i> , <i>Orthis calligramma</i> , <i>O. elegantula</i> , <i>Bellerophon bilobatus</i> , &c.	= Llandello.

¹ *Physical Geology of Ireland*, p. 22; *Knahan's Geology of Ireland*, chap. iii.; *Geological Survey of Ireland, Explanation of Sheets* (76, 77, 83, and 84).

Lower Graptolite schists (with numerous graptolites)	= Aberg in part.
Alum schists, 150 feet (= Regiones A and B of Agelmin), containing the fossils enumerated on p. 331	= Cambrian
Quartzite (Fucoids)	

Though the general resemblance of the succession of fossils in Scandinavia and in Britain is singularly close, there are, as might have been anticipated, differences in the range of species, some forms having appeared earlier or having survived later in the one region than in the other. Thus the *Pentamerus oblongus* ascends in Scandinavia into rocks full of Wenlock corals, but does not occur in the Wenlock group of Britain. On the other hand, among Scandinavian strata containing such characteristically Lower Silurian genera of trilobites as *Asaphus*, *Trinacrus*, and *Ogygia*, there occur organisms which in Britain are typically Upper Silurian, such as *Orthoceras dimidiatum* and *O. distans*, two fossils of the Ludlow rocks. This is a point of considerable importance in its bearing upon the value of palæontological evidence in correlating the formations of different countries. It shows that the order of succession found to hold good in one region cannot be rigidly applied to others, and that in such cases it is not from individual species so much as from the general facies of the fossils that we must draw geological parallels. The first appearance and duration of a species have doubtless greatly varied in different regions.

In Russia Silurian rocks must occupy the whole vast breadth of territory between the Baltic and the flanks of the Ural Mountains, beyond which they spread eastwards into Asia. Throughout most of this extensive area they lie in horizontal undisturbed beds, covered over and concealed from view by later formations. Along the flanks of the Urals they have been upheaved, and placed on end or at a high angle against the central portions of that chain, and have been partially metamorphosed into chlorite-schist, mica-schist, quartz-rock, and other crystalline masses. But along the southern margin of the Gulf of Finland they appear at the surface as soft clays, sands, and unaltered strata, which, so far as their lithological characters go, might be supposed to be of late Tertiary date, so little have they been changed during the enormous lapse of ages since Lower Palæozoic time. The great plains between the Ural chain on the east and the rising grounds of Germany on the south-west have thus from a remote geological antiquity been exempted from the terrestrial coningations which have affected so much of the rest of Europe. They have been alternately, but gently, depressed as a sea-floor, and elevated into steppes or plains. The following subdivisions have been established by P. Schmidt among the Silurian rocks of north-west Russia:—

I. Upper Silurian—

Sandy variable limestone, with marly layers passing into sandstone (<i>Zephrentis tuberculata</i> , <i>Goniatites angulatus</i> , <i>Chonetes stridella</i> , and numerous fish remains, &c.)	= Tilestones.
Upper Oesel group, yellow marl and sometimes dolomite strata (<i>Rhynchonella Nitzoni</i> , <i>Chonetes stridella</i> , <i>Platystrophia helvetica</i> , <i>Eurypterus runcipes</i> , and fish remains, &c.)	= Ludlow.
Lower Oesel group, dolomite, with marl and limestone below (<i>Protopora tabulata</i> , <i>Halysites distans</i> , <i>Bryozoa Klotzii</i> , <i>Euchinus punctatus</i> , <i>Proetus concentricus</i> , <i>Orthis laevigata</i> , <i>Spizella crispus</i> , <i>Leptæna transversalis</i> , <i>Euchinus fucatus</i> , <i>Orthoceras annulatum</i> , &c.)	= Wenlock.

II. Middle Silurian—

Pentamerus band, with <i>P. oblongus</i> (<i>oblongus</i>), <i>Alveolites labechei</i> , <i>Bellerophon diductus</i> , <i>Brontoceras signatus</i> (at Llandello).	
Compact limestone and dolomite with siliceous nodules (<i>Halysites muricatus</i> , <i>Platystrophia scutellata</i> , <i>Strophomena pretia</i> , <i>Orthis hybrida</i> , <i>Pentamerus linguifer</i> , <i>Leptæna marginata</i> , &c.)	= Llandovery.
Pentamerus band, limestone, and dolomite, with <i>Pentamerus borealis</i> , &c.	

² *Untersuchungen über die Silurische Formation von Estland, Nord-Land, and Oesel*, Dorpat, 1868.

III. Lower Silurian—

- (c) Bockholm limestones and marls (*Hyalosites labrynthicus*, *Ortholites megastoma*, *Synagophyllum organum*, *Lichas marginatus*, *Pleurohyalites dypterus*, *Orthoceras calymenense*, &c.) — **Cauloc.**
- (b) Lyskholm, yellow or grey compact limestone and marls (*Orth. tabellula*, *O. Atlantic*, *O. insularis*, &c.)
- (a) Wesenborg limestone and marl (*Orth. testudinaria*, *Encrinurus multigenuatatus*, *Lichas Eichenaldi*, &c.)
- (c) Limestone usually somewhat bituminous, with partings of reddish yellow and brown very bituminous marl (*Beyrichia complicita*, *Asaphus acuminatus*, *Orth. calligramma*, *Lepidoceras* sp. loca, &c.) — **Llandello.**
- (b) Orthoceras limestone and marl bands, 15 to 40 feet thick (*Monticulipora petropolitana*, *Echinostrophites arcuatum*, *Asaphus expansus*, *Orth. calligramma*, *Orthoceras rugulatum*, &c.)
- (a) Limestone, full of glauconitic grains, especially towards the bottom (*Orth. calligramma*, *O. elegans*, abundant fragments of *Urolophus*, &c.)
- (d) Glauconite sand (8 feet), with numerous Foraminifera in the glauconite grains (*Pandora cilla*, *Cynobolus*, *Trochammina*, &c.) and the "Conodonts" of Pandel. — **Arenig.**
- (c) Alum-slate (10 feet), highly carbonaceous, with pyrite-nodules and abundant graptolites (*Dicyonema Hiserupii*, *Obolus*, &c.)
- (b) Ungulite sandstone (120 feet), yellow to white, with (in the upper part) abundant shells of *Obolus Apollinis* ("Ungulites" of Pandel).
- (a) Blue clay, with sandstone bands, sparingly fossiliferous, bored at Revel to a depth of 800 feet without its bottom being reached.

In the centre and south of Europe by the most important Silurian area is the basin of Bohemia, so admirably worked out by M. Barrande in his great work already cited (p. 323), where the formations are grouped as in the subjoined table—

Upper Silurian	3d Fauna	Etage H Shales with coaly layers and beds of quartzite (<i>Phacops fenestrata</i> , <i>Tentaculites elegans</i>), with species of <i>Lepidoceras</i> , <i>Orthoceras</i> , <i>Lituites</i> , <i>Goniatites</i> , &c.	850 ft.
		" G Argillaceous limestones with chert, shales, and calcareous nodules	1000 "
		Numerous trilobites of the genera <i>Dalmanites</i> , <i>Bionites</i> , <i>Phacops</i> , <i>Proetus</i> , <i>Harpes</i> , and <i>Calymene</i> ; <i>Atrypa reticularis</i> , <i>Pentamerus linguifer</i> .	
Lower Silurian	2d Fauna	" F Pale and dark limestone with chert, <i>Harpes</i> , <i>Lichas</i> , <i>Phacops</i> , <i>Atrypa reticularis</i> , <i>Pentamerus pectatus</i> , <i>Favosites Gothlandicus</i> , <i>F. fibrosa</i> , <i>Tentaculites</i> .	
		" E Shales with calcareous nodules, and shales resting on sheets of igneous rock (300 ft.)	450-900 "
		A very rich Upper Silurian fauna, abundant cephalopods, trilobites, &c.; <i>Hyalosites entellianus</i> , graptolites many species	
Azoic Cambrian.	1st Fauna	" D Yellow, grey, and black shales, with quartzite and conglomerate at base	3000 "
		Abundant trilobites of genera <i>Trinucleus</i> , <i>Oryzopsis</i> , <i>Asaphus</i> , <i>Ilmenius</i> , <i>Remopleurides</i> , &c.	
		" C Shales or "schists" sometimes with porphyries and conglomerates	900-1200 "
Azoic Cambrian.	1st Fauna	<i>Pentadozides</i> , <i>Ellipsocephalus</i> , <i>Agrostites</i> , and other genera of trilobites referred to above (ante, p. 330).	
		" B Schists wholly unfossiliferous resting on bottom gneiss.	
		" A on bottom gneiss.	

The lower two *étages* (A, B) correspond probably to some of the older parts of the British Cambrian series, and perhaps in part to still older rocks. Etage C, or the Primal Zone, is the equivalent of the Upper Cambrian rocks of Wales, possibly also partly of the Arenig series. Etage D, subdivided into five groups (*d1*, *d2*, *d3*, *d4*, and *d5*), appears to be, on the whole, representative of the Lower Silurian formations of the British area, though it is impossible to make the minor subdivisions in the two countries agree. The

remaining four formations answer to the English and Welsh Upper Silurian series,—the highest zone of all (H) indicating by its organic remains the approach of the Devonian series.

Small though the area of the Silurian basin of Bohemia is (for it measures only 100 miles in extreme length by 44 miles in its greatest breadth), it has proved extraordinarily rich in organic remains. M. Barrande has named and described above 2000 species from that basin alone, the greater number being peculiar to it. Some aspects of its organic faunas are truly remarkable. One of these is the extraordinary variety and abundance of its straight and curved cephalopods. M. Barrande has determined 18 genera and 2 sub-genera, comprising in all no fewer than 1127 distinct species. The genus *Orthoceras* alone contains 554 species, and *Cytoeceras* has 330! The trilobites likewise appear in great numbers, the same indubitable explosion having detected as many as 42 distinct genera, comprising 350 species. Of these the most prolific genus is *Bionites*, which includes 46 species entirely confined to the 3d fauna or Upper Silurian. *Acidaspis* has 49 species, of which 8 occur in the 2d and 3d in the 3d fauna. *Proetus* also numbers 40 species, which all belong to the 3d fauna, save 2 found in the 2d. Other less prolific but still abundant genera are *Dalmanites*, *Phacops*, and *Ilmenius*. The 2d fauna, or Lower Silurian rocks, contain in all 32 genera and 127 species of trilobites, while the 3d fauna, or Upper Silurian formations, contain 17 genera and 205 species, so that generic types are more abundant in the earlier and specific varieties in the later rocks.

In Germany Silurian rocks appear in a few detached areas, but present a great contrast to those of Bohemia in their comparatively unfossiliferous character, and the absence of any one continuous succession of the whole Silurian system. They occur in the Thüringer Wald, where a series of fossiliferous schists (perhaps Cambrian) passes up into slates, greywackes, &c., with *Lingula*, *Dicella*, *Calymene*, numerous graptolites, and other fossils. These strata (from 1600 to 2000 feet thick) may represent the Lower Silurian formations. They are covered by some graptolitic aluminous slates, shales, flinty slates, and limestones (*Favosites Gothlandica*, &c.), which no doubt represent the Upper Silurian, and pass into the base of the Devonian formations. Among the Harz Mountains certain greywackes and shales containing land-plants (*Lycopteris*, &c.), trilobites (*Dalmanites*, &c.), graptolites, &c., are regarded as of intermediate age between true Upper Silurian and Lower Devonian rocks. In the north-west of France an impoverished series of sandstones and slates represents the succession of formations up to the top of the Silurian or base of the Devonian system, and contains a suite of trilobites which indicate more analogy with the Silurian fauna of Bohemia and of Spain than with that of the British Island. In the western half of the Spanish peninsula Silurian rocks are found flanking the older schists and crystalline masses, and spreading over a vast area of the tableland. They appear to belong chiefly if not wholly to the lower division of the system, and they include representatives of Barrande's primordial zone, containing 19 species of organisms, of which 9 are primordial trilobites.

NORTH AMERICA.—In the United States and Canada the Silurian formations spread continuously over a vast territory, from the mouth of the St Lawrence southwards into Alabama and westwards by the great lakes. They almost encircle and certainly underlie all the later Palæozoic deposits of the great interior basin. The rocks are most typically developed in the state of New York, where they have been arranged as in the subjoined table.

D. Upper Silurian.

IV. Oriskany Formation.	Oriskany sandstone (<i>Spirifer oncosus</i>).	
	(4) Upper Pentamerus limestone (<i>Pentamerus pseudogaleatus</i>)	
III. Lower Helderberg Formation.	(3) Delthyris limestone (<i>Meristella tenuis</i>)	
	(2) Lower Pentamerus limestone (<i>Pentamerus galeatus</i>)	Ladlow.
	(1) Water-lime (<i>Tentaculites</i> , <i>Eurypterus</i> , and <i>Pterygotus</i>)	
II. Salina Formation.	Onondago salt group, nearly barren of fossils.	
	(3) Niagara shale and limestone (<i>Hyalosites</i> , <i>Favosites</i> , <i>Calymene Blumenbachii</i> , <i>Homalotulus delphoccephalus</i> , <i>Lepidoceras transversus</i> , &c.)	Wenlock.
I. Niagara Formation.	(2) Clinton group (<i>Pentamerus oblongus</i> , <i>Atrypa reticularis</i> , &c.)	Upper Lland-dowry.
	(1) Medina group with Onondaga conglomerate (<i>Micetolopsis orthoceras</i>)

- A. Lower Silurian.*
- | | | | | | | |
|------------------------|--|--|---|--|-------------------|--|
| II. Trenton Formation. | (3) Onondaga (Hudson River) group (<i>Syringopora, Halysites, Dyplogaphys piratis, Pterinea denusca, Leptaena sericea</i>) | (2) Utica group—Utica shale. | Trenton limestone | Black River limestone | Burlsey limestone | { <i>Graptolithus amplexicaulis, Trinucleus concentricus, Orthis testudinaria, Murchisoni, Goniatites, Orthoceras, Cyrtoceras, &c.</i> |
| | | | | | | |
| I. Canadian Formation. | (3) Chazy group—Chazy limestone (<i>Maclurea magna, M. Logani, Orthoceras, Illeirus, Asaphus</i>) | (2) Quebec group (upwards of 100 species of trilobites of genera <i>Agnostus, Annyra, Amphion, Concoryphe, Dilclocephalus, Illeirus, Asaphus, &c.</i> , more than 50 species of graptolites) | (1) Calcareous group (graptolites, <i>Lungidella acuminata, Leptaena, Concoryphium, Ophileta compta, Orthoceras phragmenum</i> , 14 species of trilobites of the genera <i>Amphion, Bathyrus, Asaphus, Concoryphe</i>) | Potsdam formation, representing Cambrian (see ante, p. 331). | | |
| | | | | | | |
| | | | | | | |

The most recent researches of Mr Selwyn and his colleagues of the Geological Survey of Canada have shown that in the so-called Quebec group have been included a number of formations of very different stratigraphical positions. He recognizes in it three distinct groups:—(1) at the base a group of crystalline schists; (2) a group of sandstones and slates with abundant volcanic rocks, probably Cambrian; and (3) Lower Silurian slates, shales, limestones, quartzites, sandstones, and conglomerates. He objects to the introduction of new names to denote systems of rocks, and thinks that Laurentian, Huronian, Cambrian, and Silurian meet all present requirements.

DEVONIAN AND OLD RED SANDSTONE.

In Wales and the adjoining counties of England, where so full a development of the Silurian system was originally discovered and worked out by Murchison, the abundant marine fauna comes to an abrupt close when the red rocks set in at the top of the Ludlow group. From that horizon upwards in the geological series we have to pass through some 10,000 feet or more of barren red sandstones and marls, until we again encounter a copious marine fauna in the Carboniferous Limestone. It is evident that between the disappearance of the Silurian and the arrival of the Carboniferous fauna very great geographical changes must have occurred over the area of Wales and the west of England. The sea must have been excluded from the area, or at least must have been rendered unfit for the existence and development of marine life over the area in question. From the striking contrast between the general facies of life in the Silurian and that in the Carboniferous system it is manifest that the interval between them must have been of long duration.

The geological records of this vast interval are still only very partially unravelled and interpreted. At present the general belief among geologists is that, while in the west and north-west of Europe the Silurian sea-bed was upraised into land in such a way as to enclose large inland basins, in the centre and south-west the geographical changes did not suffice to exclude the sea, which continued to cover more or less completely that region. In the isolated basins of the north-west a peculiar type of deposits termed the Old Red Sandstone is believed to have accumulated, while in the shallow seas to the south and east a series of marine sediments and limestones was formed to which the name of Devonian has been given. It is thus supposed that the Old Red Sandstone and the Devonian represent different geographical areas, with different phases of sedimentation and of life, during the long lapse of time between the Silurian and Carboniferous periods.

That the Old Red Sandstone does really represent this prolonged interval can be demonstrated by innumerable sections in Britain, where its lowest strata are found gradu-

ating downward into the top of the Ludlow group and its highest beds are seen to pass up into the base of the Carboniferous system. But the evidence is not everywhere so clear in regard to the true position of the Devonian rocks. That these rocks lie between Silurian and Carboniferous formations is indeed sufficiently clear. But it is a curious fact that where the Lower Devonian beds are best developed the Upper Silurian formations are scarcely to be recognized, or if they occur, they can hardly be separated from the so-called Devonian rocks. It is therefore quite possible that the lower portions of what has been termed the Devonian series may in certain regions to some extent represent what are elsewhere recognized as undoubted Ludlow or even perhaps Wenlock rocks. We cannot suppose that the rich Silurian fauna died out abruptly at the close of the Ludlow epoch. We should be prepared for the discovery of younger Silurian rocks than the latest of those in Britain, such as M. Barrande has shown to exist in his Étage H. The rocks termed Lower Devonian may partly represent some of these later phases of Silurian life, if they do not also mark peculiar geographical conditions of a still older period in Upper Silurian time. On the other hand, the upper parts of the Devonian system might in several respects be claimed as fairly belonging to the Carboniferous system above.

The late Mr Jukes proposed a solution of the Devonian problem, the effect of which would be to turn the whole of the Devonian rocks into Lower Carboniferous, and to place them above the Old Red Sandstone, which would thus become the sole representative in Europe of the interval between Silurian and Carboniferous time.¹ In the following descriptions an account will first be given of the Devonian type and then of the Old Red Sandstone.

A. Devonian.

This name was first applied by Sedgwick and Murchison to the rocks of North and South Devon and Cornwall, whence a suite of fossils was obtained which Lonsdale pronounced to be intermediate in character between Silurian and Carboniferous. The relations of these strata to Silurian rocks cannot be determined from any section. They pass upward into Carboniferous strata. They have been arranged into three divisions, as in the subjoined table.

- | | | |
|-----------|---|--|
| Upper.... | { | Pilton and Pockwell-Down Group—Grey slate with courses of impure limestone (Pilton) passing down into yellow, brown, and red sandstones (Baggy Point, Mawood), and a series of hard grey and red sandstones and micaceous flagstones at the base (Pockwell-Down, Dulverton, Morto Bay) |
| | | Milcombe Group—Grey micaceous slates (Morte Hoe, Wedcombe, and Lea Bar) passing down into calcareous fossiliferous slates and limestones (Dilcombe, Combe Martin, Torquay, Plymouth) resting on hard green, grey, and red grits, sandstones, and conglomerates (Langman Hill) |
| Middle... | { | Lynton Group—Soft slates with thin limestone and sandstone bands (Lynton) resting on lowest schists and red and grey micaceous sandstones (Lynton, Lynmouth, Foreland, &c.). |
| | | |
| Lower.... | { | |
| | | |

The total fauna of the British Devonian rocks numbers about 400 species. The middle group is the chief repository of fossils.

Lower.—Among the lower gritty slates and limestone bands of North Devon there are found, according to the detailed census compiled by Mr Etheridge, 18 species of fossils, comprising *Favosites cervicornis*, *Penestella antiqua*, *Orthis arenata*, *Spirifer canaliculus*, *S. levicostus*, &c. Of these organisms 7 species are also found among the Devonian rocks of the Rhine, Belgium, or France. Mr Etheridge re-

¹ See his papers in *Journ. Roy. Geol. Soc. Ireland* (1865), i. pt. 1, new ser., and *Quart. Journ. Geol. Soc.*, xxii. (1866), and his pamphlet on *Additional Notes on Rocks of North Devon*, &c., 1867.

marks that it is singular that the British Lower Devonian rocks should only have yielded 1 gasteropod (*Pleurotomaria aspera*), 4 lamelibranchs, 1 cephalopod (*Orthoceras gracile*), and 1 nucleobranch (*Bellerophon bisulcatus*). They have furnished only 10 brachiopods. Traces of fish remains have been obtained among them in the form of bones and coprolitic debris. So far as observation has gone not a single Silurian species has been certainly detected in the Devonian rocks of Britain, with, according to Mr Etheridge, the sole exception of the long-lived and universally diffused *Atrypa reticularis*, which occurs in the Ilfracombe group. There can be no doubt, however, from the meagre list of fossils from the Lower Devonian rocks of Devon and Cornwall, that either the conditions for the existence or those for the fossilization of the early Devonian fauna must have been singularly unfavourable in the south-west of England. It would be exceedingly rash to argue as to the extinction of the Silurian fauna from the unsatisfactory evidence of these rocks.

Middle.—As above remarked, this is the great storehouse of Devonian fossils in the south-west of England. In this fauna, as tabulated by Mr Etheridge, there are 8 amorphozoans, including 5 species of *Stromatopora*, 23 genera and 50 species of coelenterates, among which the corals *Acerularia*, *Alveolites*, *Cyathophyllum*, *Pavonites*, *Pleurodictyum*, and *Petraria* are conspicuous; 4 genera and 8 species of crinoids (*Hexacrinus*, *Cyathocrinus*, &c.); 1 annelide (*Tentaculites annulatus*), 5 genera and 13 species of crustaceans, which are all trilobites (*Phacops granulatus*, *P. latifrons*, *P. punctatus*, *Brontops fiabellifer*, *Cheirurus articulatus*, *Harpes macrocephalus*, &c.); and 12 species of polyzoans. The brachiopods are abundant; 68 species have been yielded by the rocks of South Devon, including *Athyris concentrica*, *A. lachryma*, *Atrypa reticularis*, *A. desguamata*, *Umarophora rhomboidea*, *Cyrtina Lemarlii*, *Ostrea striatula*, *Rhynchonella acuminata*, *R. pugnax*. *Pentamerus brevivestris*, *Spirifer dysynctus*, *Stringocephalus Butini*, *Unctites gypphus*, &c. The lamelibranchs are poorly represented, 11 genera only occurring, and many of them represented by only 1 species. The gasteropods are likewise present in but small numbers and variety; 12 genera and 36 species have been enumerated. Of these species, 4 (*Aerocula vetusta*, *Eumphalus levis*, *Macrochelus imbricatus*, and *Murchisonia spinosa*) survived into the Carboniferous period. The cephalopods are represented by 5 genera, the most abundant specifically being *Cyrtoceras* and *Orthoceras*; *Goniatites*, *Clymenia*, and *Nautilus* also occur. Of the total list of fossils a large proportion is found in the Middle Devonian rocks of the continent of Europe. Very few species agree with those of the Silurian or with those of the Carboniferous system.

Upper.—From the calcareous portions of the Petherwin and Pilton beds of Cornwall and Devon a considerable number of fossils has been obtained. Among the more characteristic of these we find 11 species of the coiled cephalopod *Clymenia* (*C. undulata*, *C. levisgata*, *C. striata*), the trilobites *Phacops granulatus* and *P. latifrons*, the small ostracod *Cypridina serrato-strata*, the brachiopods *Spirifer dysynctus* or *Verneulli*, *Strophomena rhomboidalis*, *Chonetes Hurdensis*, *Productus subaculeatus*, and the lamelibranch *Cuculella Hardingii*. The Marwood and Baggy Piton beds have also yielded traces of land plants, such as *Knorria dichotoma* and *Adiantites Hebræicus*, the latter fern being common in some parts of the Upper Old Red Sandstone of Ireland.

The higher red and yellow sandy portions of the Upper Devonian rocks shade up insensibly at Barnstaple in North Devon into strata which by their fossils are placed at the base of the Carboniferous Limestone series. But in no other series save the south-western district of Britain can such a

passage be observed. In all other places the Carboniferous system, where its true base can be seen, passes down into the red sandy and marly strata of the Upper Old Red Sandstone without marine fossils.

CONTINENTAL EUROPE.—Devonian rocks occupy a large area in the centre of Europe, extending from the Ardennes through the south of Belgium across Rhenish Prussia to Darmstadt. They are best known from the picturesque gorges which have been cut through them by the Rhine below Bingen and by the Moselle below Treves. They have been arranged into the following groups in the Eifel region, where their true geological position was first indicated by Sedgwick and Murchison.

III. Upper Devonian.—

(a) *Cypridina* shales (*Cypridina serrato-strata*)
(b) *Goniatite* shales (*Goniatites retorsus*, & *minorialis*, *Orthoceras sublaevius*, *Cardiola retrostrata*, &c.).

(a) *Nodular* crinoidal limestone (Kramenzalkalk), dolomite marl, and shaly limestone (*Spirifer dysynctus* or *V. vernulli*, *Atrypa reticularis*, *Rhynchonella subaeolis*, *Productus subaculeatus*, &c.).

II. Middle Devonian.—

(b) *Stringocephalus* group, consisting of the great Eifel limestone with underlying crinoidal beds (*Stringocephalus Butini*, *Spirifer undatus*, *Productus subaculeatus*, *Pentamerus galactus*, *Atrypa reticularis*, *Calceola sandutina*, and many corals and crinoids).

(a) *Calceola* group,—mainly limestones full of *Calceola sandutina*, *Spirifer concentricus*, *Camaphoria mucronata*, &c., resting upon impure shaly ferruginous limestone and greywacke, marked by an abundance of *Spirifer cultrigatus*, *Rhynchonella Obliquiana*, *Atrypa reticularis*, *Phacops latifrons*, &c.

I. Lower Devonian.—

(a) Upper greywacke and shale (Vichter-Schichten), with a mixture of Lower and Middle Devonian fossils

(b) *Ahr* group,—greywacke-shales with *Chonetes sarcinulata*, *C. dilatata*, *Rhynchonella Lronica*, *Spirifer variegatus*, & *speciosus*, many species of *Pterinea*, *Pleurodictum*, and *Murchisonia*

(a) *Coelenterate* group, greywacke and clay-slate (*Leptania laticosta*, *Chonetes sarcinulata*, *Rhynchonella Lronica*, *Pleurodictum problematum*, &c.)

This threefold subdivision, with a central mass of calcareous strata, is traceable westwards through Belgium (where the *Calcaie de Givet* represents the *Stringocephalus* limestones of the Eifel) and eastwards into the Harz. The rocks reappear with local petrographical modifications, but with a remarkable persistence of general paleontological characters, in Eastern Thuringia, Franconia, Saxony, Silesia, the north of Moravia, and East Galizia. Devonian rocks have been detected among the crumpled rocks of the Styrian Alps by means of the evidence of abundant corals, clymenias, gasteropods, lamelibranchs, and other organic remains. Perhaps in other tracts of the Alps, as well as in the Carpathian range, similar shales, limestones, and dolomites, though as yet unfossiliferous, but containing ores of silver, lead, mercury, zinc, cobalt, and other metals, may be referable to the Devonian system.

In the centre of Europe, therefore, the Devonian rocks consist of a vast thickness of dark-grey sandy and shaly rocks, with occasional seams of limestone, and in particular with one thick central calcareous zone. These rocks are characterized in the lower zones by numerous broad-winged sprifers and by peculiar trilobites (*Phacops*, *Homalotulus*, &c.), which, though genealogically like those of the Silurian system, are specifically distinct. The central calcareous zone abounds in corals and crinoids as well as in numerous brachiopods. In the highest bands a profusion of coiled cephalopods (*Clymenia*) occurs in some of the limestones, while the shales are crowded with a small but characteristic ostracod, crustacean (*Cypridina*). Here and there traces of fishes have been found, more especially in the Eifel, but seldom in such a state of preservation as to warrant their being assigned to any definite place in the zoological scale. More recently, however, E. Beyrich has described from Gerolstein in the Eifel an undoubted species of *Pterichthys*, which, as it cannot be certainly identified with any known form, he names *P. Rhenanus*. A *Coccosteus* has been described by F. A. Roemer from the Harz, and more recently one has been cited from Bicken near Herborn by V. Koenen, but, as Beyrich points out, there may be some doubt as to whether the latter is not a *Pterichthys*. A *Ctenacanthus*, seemingly undistinguishable from the *C. Bohemicus* of Burmeister's Étage G, has also been obtained from the Lower Devonian "Nereitenschichten" of

Thuringia.¹ The characteristic *Holaptelichus nobilissimus* has recently been detected in the Fammitte de Condor, which in Belgium forms a characteristic sandy portion of the Upper Devonian rocks. These are interesting facts, as helping to link the Devonian and Old Red Sandstone types together. But they are as yet too few and unsupported to warrant any large deduction as to the correlations between these types.

It is in the north-east of Europe that the Devonian and Old Red Sandstone appear to be united into one system, where the limestones and marine organisms of the one are interstratified with the fish-bearing sandstones and shales of the other. In Russia, as was shown in the great work *Russia and the Ural Mountains* by Murchison, De Vaucell, and Keyserling, rocks intermediate between the Upper Silurian and Carboniferous Limestone formations cover an extent of surface larger than the British Islands. This wide development arises not from the thickness but from the undisturbed horizontal character of the strata. Like the Silurian formations above described, they remain to this day nearly as flat and unaltered as they present but a meagre representative of the massive Devonian greywacke and limestone of Germany, or of the Old Red Sandstone of Britain. Yet vast though the area is over which they form the surface rock, it is probably only a small portion of their total extent; for they are found tuned up from under the newer formations along the flank of the Ural chain. It would thus seem that they spread continuously across the whole breadth of Russia in Europe. Though almost everywhere undisturbed, they afford evidence of some terrestrial oscillation between the time of their formation and that of the Silurian rocks on which they rest, for they are found gradually to overlap Upper and Lower Silurian formations.

The chief interest of the Russian rocks of this age lies in the fact, first signalled by Murchison and his associates, that they unite within themselves the characters of the Devonian and the Old Red Sandstone types. In some districts they consist largely of limestones, in others of red sandstones and marls. In the former they present mollusks and other marine organisms of known Devonian species, in the latter they afford remains of fishes, some of which are specifically identical with those of the Old Red Sandstone of Scotland. The distribution of these two paleontological types in Russia is traced by Murchison to the lithological characters of the rocks, and consequent original diversities of physical conditions, rather than to differences of age. Indeed cases occur where in the same band of rock Devonian shells and Old Red Sandstone fishes lie commingled. In the belt of the formation which extends southwards from Archangel and the White Sea, the strata consist of sands and marls, and contain only fish remains. Traced through the Baltic provinces, they are found to pass into red and green marls, clays, thin limestones, and sandstones, with beds of gypsum. In some of the calcareous bands such fossils occur as *Orthis struthella*, *Spirifer ussuriensis*, *Leptæna productolites*, *Spirifer calcaratus*, *Spirifer anglicoides*, and *Othoceras subpyriforme*. In the higher beds *Holaptelichus* and other well-known fishes of the Old Red Sandstone occur. Followed still farther to the south, as far as the watershed between Orel and Woonesch, the Devonian rocks lose their red colour and sandy character, and become thin-bedded yellow limestones, and dolomites with soft green and blue marls. Traces of salt deposits are indicated by occasional saline springs. It is evident that the geographical conditions of the Russian area during the Devonian period must have closely resembled those of the Rhine basin and central England during the Triassic period.

The Russian Devonian rocks have been classified as follows. —

Upper.	{ Red and white sandstone and green marls — numerous fish remains, particularly <i>Holaptelichus nobilissimus</i> , <i>Glyptotus foveatus</i> , <i>Diplaterus macrocephalus</i>
Middle.	{ Limestones, clays, marls, dolomite, and gypsum — numerous characteristic Devonian shells and corals, also <i>Holaptelichus nobilissimus</i> .
Lower.	{ In some districts red and green limestones with red marls and Middle Devonian fossils, in others (North Lavonia) sandstones and clays, with numerous fish remains of the genera <i>Osteolepis</i> , <i>Dipterus</i> , <i>Diplaterus</i> , <i>Aspidolepis</i> , and others found also in the Carlisle flags of Scotland.

There is an unquestionable passage of the uppermost Devonian rocks of Russia into the base of the Carboniferous system. The Devonian rocks of North America are noticed at the end of the next section.

B. Old Red Sandstone.

Under this name is comprised a vast and still imperfectly described series of red sandstones, shales, and conglomerates, intermediate in age between the Ludlow rocks of the Upper Silurian formations and the base of the Carboniferous system

in Britain. These rocks were termed "Old" to distinguish them from a somewhat similar series overlying the Coal-measures, to which the name New Red Sandstone was applied. When the term Devonian was adopted, it speedily supplanted that of Old Red Sandstone, inasmuch as it was founded on a type of marine strata of wide geographical extent, whereas the latter term described what appeared to be merely a British and local development. For the reasons already given, however, it is desirable to retain the title Old Red Sandstone as descriptive of a remarkable suite of formations to which there is nothing analogous in typical Devonian rocks. It is in Great Britain that the Old Red Sandstone of Europe is almost entirely developed. This interesting series of deposits must from the first have been deposited in separate areas or basins, the sites of some of which can still be traced. Their diversities of sediment and discrepancy of organic contents point to the want of any direct communication between them. It was maintained many years ago by Mr Godwin Auston, and has been more recently enforced by Professor Ramsay, that these basins were lakes or inland seas. The character of the strata, the absence of unequivocally marine fossils, the presence of land-plants and of numerous ganoid fishes which have their modern representatives in rivers and lakes, suggest and support this opinion, which has been generally adopted by geologists. The red arenaceous and marly beds which, with their fish remains and land-plants, occupy a depth of many thousand feet between the top of the Upper Silurian and the base of the Lower Carboniferous formations, are regarded as the deposits of a series of lakes or inland seas formed by the uprise of portions of the Silurian sea-floor. The length of time during which these lacustrine basins must have existed is shown, not only by the thickness of the deposits formed in them, but by the complete change which took place in the marine fauna between the close of the Silurian and the commencement of the Carboniferous period. The prolific fauna of the Wenlock and Ludlow rocks was extirpated over the British area by the physical changes, which produced the lake-basins of the Old Red Sandstone. When a marine population — crinoids, corals, and shells — once more overspreads the area it is found to be completely different. So thorough a change must have demanded a long interval of time.

Murchison, who strongly advocated the opinion that the Old Red Sandstone and Devonian rocks represented different geographical conditions of the same period, and who had with satisfaction seen the adoption of the Devonian classification by Continental geologists, endeavoured to trace in the Old Red Sandstone of Britain a threefold division like that which had been accepted for the Devonian system. He accordingly arranged the formations as in the subjoined table.

Old Red Sandstone as classified by Murchison.	Upper. Middle. Lower.	{ Yellow and red sandstones and conglomerates (<i>Pterichthys major</i> , <i>Holaptelichus nobilissimus</i> , &c.) — Dana Den beds.
		{ Grey and blue calcareous and bituminous flagstones, limestones, and red sandstones, and conglomerates (<i>Dipterus</i> , <i>Osteolepis</i> , <i>Aspidolepis</i> , <i>Acanthodes</i> , <i>Pterichthys</i> , &c.) — Carlisle flags.
		{ Red and purple sandstones, grey flagstones, and coarse conglomerates (<i>Cladophaga</i> , <i>Pteraspis</i> , <i>Pteroptilus</i>) — Ayrshire flags.

It is important to observe that in no district can these three subdivisions be found together, and that the so-called "middle" formation occurs only in one region — the north of Scotland. The classification, therefore, does not rest upon any actually ascertained stratigraphical sequence, but on an inference from the organic remains. The value of this inference will be estimated a little further on. All that can be affirmed from stratigraphical evidence in any Old Red Sandstone district in Britain is that a great physical and

¹ Op. cit., 423.

paleontological break can generally be traced in the Old Red Sandstone, dividing it into two completely distinct series—a Lower, which graduates downward into the Upper Silurian, and an Upper, which passes upward into the base of the Carboniferous system.

As a whole, the Old Red Sandstone, where its strata are really red, is like other masses of red deposits, singularly barren of organic remains. The physical conditions under which the precipitation of iron oxide took place were evidently unfavourable for the development of animal life in the same waters. Professor Ramsay has connected the occurrence of such red formations with the existence of salt lakes, from the bitter waters of which not only iron-oxide but often rock-salt, magnesian limestone, and gypsum were thrown down. He points also to the presence of land-plants, footprints of amphibia, and other indications of terrestrial surfaces, while truly marine organisms are either found in a stunted condition or are absent altogether. Where the strata of the Old Red Sandstone, losing their red colour and ferruginous character, assume grey or yellow tints and pass into a calcareous or argillaceous condition, they not infrequently become fossiliferous. At the same time it is not unworthy of remark that some of the red conglomerates, which might be supposed little likely to contain organic remains, are occasionally found to be full of detached scales, plates, and bones of fishes.

Along the border of the Silurian region from Shropshire into South Wales the uppermost parts of the Silurian system graduate into a mass of red strata not less than 10,000 feet thick, which in turn pass up conformably into the base of the Carboniferous system. This vast accumulation of red rocks, termed the Old Red Sandstone, consists in its lower portions of red and green shales and flagstones, with some white sandstones and thin cornstones, in the central and chief division, of red and green spotted sandy marls and clays, with red sandstones and cornstones, in the higher parts of grey, red, chocolate-coloured, and yellow sandstones, with bands of conglomerate. No unconformability has yet been detected in any part of this series of rocks, though, from the observations of De la Beche, it may be suspected that the higher strata which graduate upward into the Carboniferous formations are separated from the underlying portions of the Old Red Sandstone by a distinct discordance.

Although, as a whole, barren of organic remains, these red rocks have here and there, more particularly in the calcareous zones, yielded fragments of fishes and crustaceans. In their lower and central portions remains of the ganoids *Cephalaspis*, *Didymaspis*, *Scaphaspis*, *Pteraspis*, and *Cyathaspis* have been found, together with crustaceans of the genera *Stylonurus*, *Pterygotus*, and *Preacurus*, and obscure traces of plants. The upper yellow and red sandstones contain none of the cephalaspid fishes, which are there replaced by *Pterichthys* and *Ilopterygius*, associated with distinct impressions of land-plants. In some of the higher parts of the Old Red Sandstone of South Wales and Shropshire, *Serpula* and *Conularia* occur; but these are exceptional cases, and point to the advent of the Carboniferous marine fauna, which doubtless existed outside the British area before it spread over the Old Red Sandstone basins.

It is in Scotland that the Old Red Sandstone shows the most complete and varied development, alike in physical structure and in organic contents. Throughout that country the system is found everywhere to present a division into two well-marked groups of strata, separated from each other by a strong unconformability and a complete break in the succession of organic remains. It occurs in distinct areas which appear to mark the site of separate basins of deposit. One of these occupies the central valley between the base of the Highland mountains and the uplands of the southern

counties. On the north-east it is cut off by the present coast-line from Stonehaven to the mouth of the Tay. On the south-west it ranges by the island of Arran across St George's Channel into Ireland, where it runs almost to the western sea-board, flanked on the north, as in Scotland, by hills of crystalline rocks and on the south chiefly by a Lower Silurian belt. Another distinct and still larger basin lies on the north side of the Highlands, but only a portion of it comes within the present area of Scotland. It skirts the slopes of the mountains along the Moray Firth and the east of Ross and Sutherland, and stretches through Caithness and the Orkney Islands as far as the south of the Shetland group. It may possibly have been at one time continued as far as the Sognefjord and Dalsfjord in Norway, where red conglomerates like those of the north of Scotland occur. There is even reason to infer that it may have ranged eastwards into Russia, for some of its most characteristic organisms are found also among the red sandstones of that country. A third minor area of deposit lay on the south side of the southern uplands over the east of Berwickshire and the north of Northumberland, including the area of the Cheviot Hills. A fourth occupied a basin on the flanks of the south-west Highlands, which is now partly marked by the terraced hills of Lorne. There is sufficient diversity of lithological and paleontological characters to show that these several areas were distinct basins, separated both from each other and from the sea.

In the central basin of Scotland between the Highlands and the southern uplands, the twofold division of the Old Red Sandstone is typically seen. The lower series of deposits attains a maximum depth of upwards of 20,000 feet. In Lanarkshire it is found to pass down conformably into the Upper Silurian rocks; elsewhere its base is concealed by later formations, or by the unconformability with which different horizons rest upon the older rocks. It is covered unconformably by every formation younger than itself. It consists of reddish-brown or chocolate-coloured, grey, and yellow sandstones, red shales, grey flagstones, coarse conglomerates, and occasional bands of limestone and cornstone. The grey flagstones and thin grey and olive shales and "calmstones" are almost confined to Forfarshire, in the north-east part of the basin, and are known as the Arbroath flags. One of the most marked lithological features in this central Scottish basin is the prodigious masses of interbedded volcanic rocks. These, consisting of porphyrite-lavas, felsites, and tuffs, attain a thickness of more than 6000 feet, and form important chains of hills, as in the Pentland, Ochil, and Sidlaw ranges. They lie several thousand feet above the base of the system, and are regularly interstratified here and there with bands of the ordinary sedimentary strata. They point to the outburst of numerous volcanic vents along the lake or inland sea in which the Lower Old Red Sandstone of central Scotland was laid down; and their disposition shows that these vents ranged themselves in lines or linear groups parallel with the general trend of the great central valley. The fact that the igneous rocks are succeeded by thousands of feet of sandstones, shales, and conglomerates, without any intercalation of lava or tuff, proves that the volcanic episode in the history of the lake came to a close long before the lake itself disappeared.

As a rule the deposits of this lake are singularly unfossiliferous, though some portions of them, particularly in the Forfarshire flagstone group, have proved rich in fish remains. In Lanarkshire about 5000 feet above the base of the system a thin band of shale occurs, containing a graptolite, *Spirorbis Levensis*, and *Orthoceras dimidiatum*,—undoubtedly Upper Silurian forms. This interesting fact serves to indicate that, though geographical changes had elevated the Upper Silurian sea-floor partly into land and

partly into isolated inland water-basins, the sea outside still contained an Upper Silurian fauna, which was ready on any favourable opportunity to re-enter the tracts from which it had been excluded. The interval of its reappearance seems to have been very brief, however, for the band of shale containing these Upper Silurian marine organisms is only a few inches thick, and the fossils have not been detected on any other horizon. With these exceptions, the fauna of the formation consists entirely of fishes and crustaceans. Nine or more species of crustaceans have been obtained, chiefly eurypterids, but including one or two phyllopoda. The large pterygotus (*P. Anglicus*) is especially characteristic, and must have attained a great size, for some of the individuals indicate a length of 6 feet with a breadth of 1½ feet. There occur also a smaller species (*P. minor*), two *Eurypters*, three species of *Stylonurus*, and abundant clusters of crustacean egg-packets termed *Pavina decipiens*. Seventeen species of fishes have been obtained, chiefly from the Arbroath flags. They belong to the suborders *Acanthodidae* and *Ostracosteii*. One of the most abundant forms is the little *Acanthodes Michelli*. Another common fish is *Diplacanthus gracilis*. There occur also *Cimnatus scutiger*, *C. reticulatus*, and *C. uncinatus*, *Pareus incurvus*, *Euthacanthus* (four species), *Cephalaspis Lyelli*, and *Pteraspis Michelli*. Some of the sandstones and shales are crowded with indistinctly preserved vegetation, occasionally in sufficient quantity to form thin laminae of coal. In Forfarshire the surfaces of the shaly flagstones are now and then covered with linear grass-like plants like the sedgy vegetation of a lake or marsh. In Perthshire certain layers occur chiefly made up of compressed stems of *Psilophyton*. The adjoining land was doubtless clothed with a flora in large measure lycopodiaceous.

The Old Red Sandstone of the northern basin is typically developed in Caithness, where it consists chiefly of the well-known dark-grey bituminous and calcareous flagstones of commerce. It rests unconformably upon the metamorphosed Lower Silurian schists, and must have been deposited on the very uneven bottom of a sinking basin, seeing that occasionally even some of the higher platforms are found resting against the schists and granites. The lower zones consist of red sandstones and conglomerates which graduate upward into the flagstones. Other red sandstones, however, supervene in the higher parts of the system. The total depth of the series in Caithness has been estimated at upwards of 16,000 feet.

Murchison was the first to attempt the correlation of the Caithness flagstones with the Old Red Sandstone of the rest of Britain. Founding upon the absence from these northern rocks of the characteristic cephalaspidean fishes of the admitted Lower Old Red Sandstone of the south of Scotland and of Wales and Shropshire, upon the presence of numerous genera of fishes not known to occur in the true Lower Old Red Sandstone, and upon the discovery of a *Pterygotus* in the basement red sandy group of strata, he concluded that the massive flagstone series of Caithness could not be classed with the Lower Old Red Sandstone, but must be of younger date. He supposed the red sandstones, conglomerates, and shales at the base, with their *Pterygotus*, to represent the true Lower Old Red Sandstone, while the great flagstone series with its distinctive fishes was made into a middle division answering in some of its ichthyolithic contents to the Middle Devonian rocks of the Continent. This view has been accepted everywhere by geologists. Recently, however, it has been called in question by Professor Geikie, who gives reasons for maintaining the Caithness flagstones to be Lower Old Red Sandstone, and for denying the existence of any middle division. He shows that the discrepancy in organic contents between the Caithness and the Arbroath flags is by no means so strong

as Murchison supposed, but that several species are common to both. In particular, he finds that the characteristically Lower Old Red Sandstone and Upper Silurian crustacean genus *Pterygotus* occurs, not merely in the basement zone of the Caithness flags, but also high up in the series. The genera *Acanthodes* and *Diplacanthus* are abundant both in Caithness and in Forfarshire. *Pareus incurvus* occurs in the northern as well as the southern basin. It is contended that the paleontological distinctions are not greater than the striking lithological differences between the strata of the two regions would account for, or than the contrast between the ichthyic faunas of contiguous water-basins at the present time.

Somewhere about 60 species of fishes have been obtained from the Old Red Sandstone of the north of Scotland. Among these the genera *Acanthodes*, *Asterolepis*, *Chevracanthus*, *Cheirolepis*, *Coccosteus*, *Diplacanthus*, *Diplopterus*, *Dipterus*, *Glyptolepis*, *Osteolepis*, and *Pterichthys* are especially characteristic. Some of the shales are crowded with the little ostracod crustacean *Estheria membranacea*. Land-plants abound, especially in the higher groups of the flagstones, where forms of *Psilophyton*, *Lepidodendron*, *Stigmaria*, *Sigillaria*, *Calamite*, and *Cyclopteris*, as well as other genera, occur. In the Shetland Islands traces of abundant contemporaneous volcanic rocks have been observed, which, with the exception of two trifling examples in the region of the Moray Firth, are the only known instances of volcanic action in the Lower Old Red Sandstone of the north of Scotland. In the other two Scottish basins, those of the Cheviot Hills and of Lorne, volcanic action continued long vigorous, and produced thick piles of lava like those of the central basin above referred to.

The Upper Old Red Sandstone consists in Scotland of red sandstones, clays or mals, conglomerates, and breccias, the sandstones sometimes becoming yellow or even white. These strata, wherever their stratigraphical relations can be distinctly traced, lie unconformably upon the lower division of the system, and pass up conformably into the Carboniferous rocks above. If they are studied from the side of the underlying formation, they seem naturally to form part of the Old Red Sandstone, since they agree with it in general lithological character and also in containing some distinctively Old Red Sandstone genera of fishes, such as *Pterichthys* and *Holoptichthys*. But, approached from the upper or Carboniferous direction, they appear rather to form the natural sandy base of that system into which they insensibly graduate. On the whole, they are remarkably barren of organic remains, though in one locality—Dunn Den in Fife—they have yielded a number of genera and species of fishes, crowded profusely through the pale sandstone as if the individuals had been suddenly killed and rapidly covered over with sediment. Among the characteristic organisms of the Scottish Upper Old Red Sandstone are *Pterichthys major*, *Holoptichthys nobilissimus*, *H. Andersoni*, *Glyptopomus*, *Glyptocampus*, and *Phaneropleuron*.

An interesting fact deserves mention here as a corollary to what has been stated above regarding the survival for some time of an Upper Silurian fauna outside the area of the British Old Red Sandstone lakes. In the Upper Old Red Sandstone of the basin of the Firth of Clyde, *Pterichthys major* and *Holoptichthys* occur at the Heads of Ayr, while a band of marine limestone lying in the heart of the red sandstone series in Arran is crowded with ordinary Carboniferous Limestone shells, such as *Productus giganteus*, *P. semireticulatus*, *P. punctatus*, *Chonetes Hardrensis*, *Spirifer lineatus*, &c. None of these fossils has been detected in the great series of red sandstones overlying the limestone. They do not reappear till the limestones at the base of the Carboniferous series; yet the organisms must have been living during all that long interval outside

of the Upper Old Red Sandstone area. Not only so, but they must have been in existence long before the formation of the thick Arran limestone, though it was only during the comparatively brief interval represented by that limestone that geographical changes permitted them to enter the Old Red Sandstone basin and settle for a while on its floor. Thus we see that while, on the one hand, the older parts of the Lower Old Red Sandstone were coeval with an Upper Silurian fauna which, having disappeared from the area of Britain, survived outside of that area, on the other hand, the higher parts of the Upper Old Red Sandstone were contemporaneous with a Carboniferous Limestone fauna which, having appeared beyond the British area, was ready to spread over it as soon as the conditions became favourable for the invasion. It is, of course, obvious that such an abundant and varied fauna as that of the Carboniferous Limestone cannot have come suddenly into existence at the period marked by the base of that formation. It must have had a long previous existence outside the present area of the deposits. But it is seldom that we obtain such clear evidence of the fact as in these instances from the Scottish Old Red Sandstone.

In the north of Scotland, on the lowlands bordering the Moray Firth, and again in the island of Hoy, one of the Orkney group, yellow and red sandstones, sometimes containing characteristic Upper Old Red Sandstone fishes, are found lying unconformably upon the Caithness flags. In these northern tracts the same relation is thus traceable as in the central counties between the two divisions of the system.

Turning southward across the border districts, we trace the red sandstones and conglomerates of the Upper Old Red Sandstone lying unconformably on Silurian rocks and Lower Old Red Sandstone. Some of the brecciated conglomerates have much resemblance to glacial detritus, and it has been suggested that they have been connected with contemporaneous ice-action. Such are the breccias of the Lammernuir Hills, and those which show themselves here and there from under the overlying mass of Carboniferous strata which flanks the Silurian hills of Cumberland and Westmoreland. Red conglomerates and sandstones appear interruptedly at the base of the Carboniferous rocks even as far as Flintshire and Anglesea. They are commonly classed as Old Red Sandstone, but merely from their position and lithological character. No organic remains have been found in them. They may therefore, in part at least, be taken as the basement beds of the Carboniferous system.

In Devonshire, at Barnstaple, Pilton, Marwood, and Baggy Point, certain sandstones, shales, and limestones (already referred to in the account of the Devonian rocks) graduate upward into the base of the Carboniferous system, and appear to represent the Upper Old Red Sandstone of the rest of Britain. They contain land plants and also many marine fossils, some of which are common Carboniferous forms. They thus indicate a transition into the geographical conditions of the Carboniferous period, as is still more clearly illustrated by the corresponding strata in Scotland.

NORTH AMERICA.—The Devonian system, as developed in the northern States, and eastern Canada and Nova Scotia, presents much geological interest in the union which it contains of the same two distinct petrographical and biological types found in Europe. If we trace the range of these rocks along the Allegheny chain through Pennsylvania into New York, we find them to contain a characteristic suite of marine organisms comparable with those of the Devonian system of Europe. But on the eastern side of the great range of Silurian hills in the north-eastern States, we encounter in New Brunswick and Nova Scotia a succession of red and yellow sandstones, limestones, and shales nearly devoid of marine organisms, yet full of land-plants, and with occasional traces of fish remains.

The marine or Devonian type has been grouped in the following subdivisions by the geologists of New York—

Upper Devonian	Catskill Red Sandstone.
	Chemung group
	Portage group
	Genesee group
	Hamilton group
Lower Devonian	Marcellus group
	Coniferous or Upper Helderberg group.
	Schoharie Grit
	Canda-gall Grit.

In the Lower Devonian series traces of testinital plants (*Psilophyton*, *Caulopteris*, &c.) have been detected even as far west as Ohio. Corals (cyathophylloid forms, with *Favosites*, *Syringopora*, &c.) abound, especially in the Corniferous Limestone, which is perhaps the most remarkable mass of coral-rock in the American Palaeozoic series. Among the bachiopods are species of *Pentamerus*, *Strobilodonta*, *Rhynchonella*, and others, with the characteristic European form *Spirifer cultus*, and the world-wide *Atrypa reticularis*. The trilobites include the genera *Dalmanites*, *Proetus*, and *Phacops*. The earliest known traces of American fishes occur in the Corniferous group. They consist of ichthyodontoide, and teeth of estacodont and hyodont blades, and plates, bones, and teeth of some peculiar ganoids (*Macropetalichthys*, *Oncichthys*).

In the Hamilton formation (embracing the Marcellus shale, the Hamilton beds, and the Genesee shale) remains of land-plants occur, but much less abundantly than among the rocks of New Brunswick. Bachiopods are especially abundant among the sandy beds in the centre of the formation. They comprise, as in Europe, many broad-winged spifers (*S. microretus*, &c.), with species of *Productus*, *Chonetes*, *Athyris*, &c. The earliest American ganoides have been noticed in these beds. Newberry has described a gigantic fish (*Dusichthys*) from the Black Shale of Ohio.

The Portage and Chemung groups have yielded land-plants and faunas, also some corals, numerous broad-winged spifers, with *Avicula*, and a few other lamellibranchs. These strata consist in the New York region of shales and laminated sandstones, which attain a maximum thickness there of upwards of 2000 feet, but die out entirely towards the interior. They are covered by a mass of red sandstones and conglomerates—the Catskill group, which is 2000 or 3000 feet deep in the Catskill Mountains, and thins out along the Appalachian region to 5000 or 6000 feet. These red arenaceous rocks bear a striking similarity in their lithological and biological characters to the Upper Old Red Sandstone of Europe. As a whole they are infossiliferous, but they have yielded some ferns like those of the Upper Old Red Sandstone of Ireland and Scotland (*Cyclogenia*), and some characteristic genera of fish, as *Zolotykeus* and *Bathyratops*.

Turning now to the eastern side of the ancient Laurentian and Silurian ridges, which, stretching southwards from Canada, separated in later Palaeozoic time the great interior basin from the Atlantic slopes, we find the Devonian rocks of New York, Pennsylvania, and the interior represented in New Brunswick and Nova Scotia by a totally different series of deposits. The contrast strikingly recalls that presented by the Old Red Sandstone of the north of Scotland and the Devonian rocks of North Germany. On the south side of the St Lawrence the coast of Gaspé shows rocks of the Quebec group unconformably overlaid by grey limestones with green and red shales, attaining, according to Logan, a total thickness of about 2000 feet,¹ and replete in some bands with Upper Silurian fossils. They are conformably followed by a vast arenaceous series of deposits termed the Gaspé Sandstones, to which the careful measurements of Logan and his colleagues of the Canadian Geological Survey assign a depth of 7036 feet. This formation consists of grey and diab-coloured sandstones, with occasional grey shales and bands of massive conglomerate. Similar rocks reappear along the southern coast of New Brunswick, where they attain a depth of 9500 feet, and again on the opposite side of the Bay of Fundy. The researches chiefly of Dr J. W. Dawson have shown that these strata contain an abundant terrestrial flora

—the oldest of which any relics have yet been recovered, for the few Upper Silurian land-plants at present known hardly deserve to be reckoned as a known flora. In his recent census he enumerates 110 fewer than 118 species of land-plants. They are almost all acrogens, the lycopsids and ferns being largely predominant. Among the distinctive forms the following may be mentioned—*Psilophyton*, *Arthropostema*, *Lepidophleum*, and *Protolacaria*. Fossiliferous ferns are given, including the genera *Cyclopteris*, *Nepotopsis*, *Sphenopteris*, and some triletes (*Psaronius*, *Caulopteris*). Lepidodendroid and sigillarioid plants abound, as well as calamites. Higher forms of vegetation are represented by a few conifers (*Dadoxylon*, *Ormosylon*, *Protolacaria*, &c.). From a locality on Lake Erie, Dr Dawson describes a fragment of dicotyledonous wood, not unlike that of some modern trees—the most ancient

¹ *Geology of Canada*, p. 393.

fragment of an angiospermous exogen yet discovered. So abundant are these vegetable remains that in some layers they actually form thin seams of coal.

The interest of these remains of the most venerable American forests is heightened by the discovery of the fact that they were not without the hum of insect life. The most ancient known relics of insect forms have been recovered from the Devonian strata of New Brunswick. They are all nematoporous wings, and have been identified by Mr. Scudder of Boston to four species combining a remarkable union of characters now found in distinct orders of insects. In one fragment he observed a structure which he could only compare to the stultidating organ of some male *Othoptera*. Another wing indicates the existence of a gigantic *Phaneroptera*, with a spread of wing extending to 6 inches. In the shallow pools of the period some small crinaceans lived, the remains of which have been partially preserved. Among these is a minute, shrimp-like *Ela pheros*, and a more highly organized form named *Amphipellets*. That the sea had at least occasional access to the inland basins into which this abundant terrestrial vegetation was washed is proved by the occurrence of marine organisms, such as a small annelid (*Spirorbis*) adhering to the leaves of the plants, and (in Gaspé and Nova Scotia) by the occasional appearance of brachiopods, especially *Lingula*, *Spirifer*, and *Chonetes*.¹

CARBONIFEROUS.

This great system of rocks has received its name from the seams of coal which form one of its distinguishing features both in Europe and in North America. In Europe it is most completely developed in the British Islands. Elsewhere on that continent it occurs in patches, either lying in hollows of older rocks, or exposed by the removal of overlying formations.

GREAT BRITAIN.—The area within which the Carboniferous rocks of Britain occur is sufficiently extensive to contain more than one type of the system, and thus to cast much light on the varied geographical conditions under which these rocks were accumulated. In prosecuting the study of this part of British geology, it is soon discovered, and it is essential to bear in mind, that, during the Carboniferous period, the land whence the chief supplies of sediment were derived rose mainly to the north and north-west, as it seems to have done from very early geological time. While therefore the centre and south of England lay under clear water of moderate depth, the north of the country and the south of Scotland were covered by shallow water, which was continually receiving sand and mud from the adjacent northern land. Hence vertical sections of the Carboniferous formations of Britain differ greatly according to the districts in which they are taken. The subjoined table may be regarded as expressing the typical subdivisions which can be recognized, with modifications, in all parts of the country.

Coal-measures . . .	Red and grey sandstones, clays, and sometimes <i>Mercurius</i> , with occasional seams and streaks of coal and <i>Spirorbis</i> limestone (<i>Cythere inflata</i> , <i>Spirorbis carbonarius</i>).
	Middle or chief coal-bearing series of yellow sandstones, clays, and shales, with numerous workable coals (<i>Anthracopus</i> , <i>Anthracomya</i> , <i>Deyrichia</i> , <i>Ecleria</i> , <i>Syringia</i> , &c.).
Millstone Grit . . .	Gannister beds, flagstones, scales, and thin coals, with hard siliceous (gannister) pavements (<i>Orthoceras</i> , <i>Gomastrea</i> , <i>Pseudina</i> , <i>Aviculapecten</i> , <i>Lingula</i> , &c.).
	Grits, flagstones, and shales, with thin seams of coal.
Carboniferous Limestone series . . .	Yoredale group of shales and grits passing down into dark shales and limestones (<i>Gomastrea</i> , <i>Aviculapecten</i> , <i>Pseudina</i> , <i>Lingula</i> , <i>Dorsina</i> , &c.).
	Thick limestone in south and centre of England and Ireland, passing northwards into sandstones, shales, and coals (abundant corals, <i>polyzoans</i> , brachiopods, lamellibranchs, &c.).
	Lower Limestone Shale of south and centre of England (marine fossils like those of overlying limestone), passing northward into the Calciferous Sandstone group of Scotland (marine, estuarine, and terrestrial organisms).

In the article COAL (vol. vi. p. 49) an account has been given of the principal coal-fields of the world, likewise a diagram (p. 48) representing the chief subdivisions of the Carboniferous system in Britain, as the rocks are traced from north to south.

Base of the System.—In the south-west of England, and in South Wales, the Carboniferous system passes down conformably into the Old Red Sandstone. The passage beds consist of yellow, green, and reddish sandstones, of green, grey, red, blue, and variegated marls and shales, sometimes full of terrestrial plants. They are well exposed on the Pembroke-shire coasts, marine fossils being there found even among the argillaceous beds at the top of the Red Sandstone series. They occur with a thickness of about 500 feet in the gorge of the Avon near Bristol, but show less than half that depth about the Forest of Dean. At their base there lies a bone-bed containing abundant palatal teeth. Not far above this horizon plant-bearing strata are found. Hence these rocks bring before us a mingling of terrestrial and marine conditions. In Yorkshire, near Lowther Castle, Brough, and in Ravenstonedale, alternations of red sandstones, shales, and clays, containing *Stigmara* and other plants, occur in the lower part of the Carboniferous Limestone. Along the eastern edge of the Silurian hills of the Lake district the Old Red Sandstone appears here and there, and passes up through a succession of red and grey sandstones, and green and red shales and marls, with plants, into the base of the Carboniferous Limestone.

It is in Scotland, however, that this peculiar type of the basement Carboniferous rocks is best seen. In that country the lowest subdivision of the Carboniferous system, known as the Calciferous Sandstones, consists of red, white, and yellow sandstones, blue, grey, green, and red marls or clays, blue and black shales, thin coals, seams of limestone and cement-stone, and abundant volcanic rocks. The red sandstones lie at the base, and pass down into the Upper Old Red Sandstone, in which, as has been already pointed out (ante, p. 344), true Upper Old Red Sandstone fishes are found, while there occur also bands of limestone full of true Carboniferous Limestone corals and brachiopods. Hence it is evident that the Carboniferous Limestone fauna had already appeared outside the British area before the close of the Old Red Sandstone period. It was when the peculiar geographical conditions which prevailed during that period finally ceased, and the sea began to spread over the ancient lakes and land of Britain, that the abundant Carboniferous fauna invaded the area. The Calciferous Sandstones of Scotland may therefore represent a portion of the Carboniferous Limestone of England.

Over the greater part of the south and centre of Scotland the lower red sandstones are surmounted by a series of contemporaneous volcanic rocks. Successive sheets of porphyrites and tuffs form long ranges of hills from Arran and Bute on the west to the mouth of the estuary of the Forth on the east, and from the Campsie Fells on the north to the heights of Liddesdale and the English border. These volcanic sheets sometimes reach a thickness of 1500 feet. That they belong to the Carboniferous system is shown by the occurrence of shales and sandstones (with Carboniferous plants) at their base. They show that the early part of the Carboniferous period in Scotland was marked by a prodigious volcanic activity, which, on its cessation, was followed by the prolonged subsidence required for the accumulation of the Carboniferous system. The rocks succeeding the volcanic zone are termed the cement-stone group. In Berwickshire and the west of Scotland they consist of thin bedded white, yellow, and green sandstones, grey, green, blue, and red clays and shales, with thin bands of a pale argillaceous limestone or cement-stone. Seams of gypsum occasionally appear. These strata are, on the whole,

¹ Dawson's *Canadian Geology*, chaps. xxi. and xxv.

singularly barren of organic remains. They seem to have been laid down with great slowness, and without disturbance, in enclosed basins, which were not well fitted for the support of animal life, though fragmentary plants serve to show that the adjoining slopes were covered with vegetation.

In the basin of the Firth of Forth, however, the group presents a different lithological aspect and is abundantly fossiliferous. It there usually consists of yellow, grey, and white sandstones, with blue and black shales, clay-ironstones, limestone, "cement-stones," and occasional seams of coal. The sandstones form excellent building stones, the city of Edinburgh having been built of them. Some of the shales are so bituminous as to yield, on distillation, from 30 to 40 gallons of crude petroleum to the ton of shale, they are consequently largely worked for the manufacture of mineral oils. The limestones are usually dark, yellow, and close grained, in seams seldom more than a few inches thick, and graduate by addition of carbonate of iron into cement-stone, but occasionally they swell out into thick lenticular masses like the well-known limestone of Burtle House, so long noted for its remarkable fossil fishes. This limestone appears to be mainly made up of the crowded cases of a small ostracod cystacean (*Lepidodonta obsca*, var. *Solea-Fu-dongensis*). The coal-seams are few and commonly too thin to be workable, though one of them, known as the Houston coal, has been mined to some extent in Lanthguishine. The fossils of the cement-stone group indicate an alternation of fresh or brackish-water and marine conditions. They include numerous plants, of which the most abundant are *Sphenopteris affinis*, *Lepidodendron* (two of the species), *Lepidodendron variabilis*, *Asplenium variegatum*. Some of the shales near Edinburgh have afforded a few specimens of a true monotypic nautilus allied to the modern *Pelios* (*Peliosites Grantow*). Ostracod cystaceans, chiefly the *Lepidodonta* above mentioned, crowd many of the shales. With these are usually associated abundant traces of the presence of fish, either in the form of cephalons or of scales, bones, plates, and teeth. The following are characteristic species: *Elonichthys striatulus*, *R. Robisoni*, *Rhadonichthys ornatus*, *Amatophichthys Greenocki*, *Eurypterus arcuatus*, *Illicus Hübneri*, *Megachthys* sp., *Gyracanthus tuberculatus*, *Ctenophthalmus pedicularis*. At intervals throughout the group marine horizons occur, usually as shale bands marked by the presence of such distinctively Carboniferous Limestone species as *Spilopis carbonarius*, *Dicyna nitida*, *Lingula squamiformis*, *Bellerophon decussatus*, and *Orthoceras cylindraceum*.

One of the most interesting features in the cement-stone group of the basin of the Firth of Forth is the prodigious number and variety of the associated volcanic masses, and the proofs which they exhibit that, at the time when that group of strata was accumulating, the region of shallow lagoons, islets, and coal-groves was dotted over with innumerable active volcanic vents. The eruptions continued into the time of the Carboniferous Limestone, but ceased before the deposition of the Millstone Grit. The lavas are chiefly varieties of basalt-rocks, sometimes coarsely crystalline and even granitoid in texture, and graduating through intermediate stages to true close-grained compact basalts, which neither externally nor in microscopic structure differ from basalt of Tertiary date.

The basement group of the Carboniferous system in Ireland is evidently a prolongation of the Scottish cement-stone group. In the south of this island, however, a very distinct and peculiar development of the Lower Carboniferous rocks is to be remarked. Between the top of the Old Red Sandstone and the base of the Carboniferous Limestone there occurs in the county of Cork an enormous mass (fully 5000 feet) of black and dark-grey shales, impure limestones, and grey and green grits and true cleaved slates. To these rocks the name of Carboniferous Slate was given by Griffith. They contain numerous Carboniferous Limestone species of brachiopods, echinoderms, &c., as well as traces of land-plants in the grit bands. Great though their thickness is in Cork, they rapidly change their lithological character, and diminish in mass as they are traced away from that district. In the almost incredibly short space of 15 miles, the whole of the 5000 feet of Carboniferous Slate of Bantry Bay have disappeared, and at Kenmare the Old Red Sandstone is followed immediately and conformably by the Limestone with its underlying shale. Mr

Jukes held that the Carboniferous Slate is the equivalent of part of the Devonian rocks of Devon and Cornwall.

Carboniferous Limestone.—The Lower Limestone shale is overlaid conformably by a thick mass of limestone, one of the most distinctive members of the British Carboniferous system. On referring to a geological map of England it will be seen that from Northumberland southwards to the low plains in the centre of England there runs a ridge of high ground, formed by a great anticline, along which the Carboniferous Limestone appears at intervals from underneath higher members of the system. In this northern Carboniferous area, of which the axis is known as the Pennine Chain, the limestone attains its maximum development. In one portion of the district it reaches a depth of 4000 feet, and yet its actual base is nowhere seen. This Pennine region appears to have been the area of maximum depression during the early part of the Carboniferous period in Britain. Traced towards the south west, the limestone diminishes to sometimes not more than 500 feet in South Wales. Northwards, losing its character as a massive calcareous formation, it is split up by intercalations of sandstone, shale, coal, &c., until actual limestone becomes a very subordinate member of the series in central Scotland.

In the Carboniferous areas of the south-west of England and South Wales, the limits of the Carboniferous Limestone are well defined by the Limestone Shale below, and by the Farewell Rock or Millstone Grit above. In the Pennine area, however, the massive limestone is succeeded by a series of shales, limestones, and sandstones, known as the Yoredale group. These cover a large area and attain a great thickness. In North Staffordshire they are 2300 feet, which, added to the 4000 feet of limestone below, gives a depth of 6300 feet for the whole Carboniferous Limestone series of that region. In Lancashire the Yoredale rocks attain still more stupendous dimensions, Mr Hull having found them to be no less than 4500 feet thick. Both the lower or main (Saur) limestone and the Yoredale group pass northwards into sandstones and shales, with coal-seams, and diminish in thickness. It is not impossible, as already suggested, that the cement-stone group of the Carboniferous Sandstones of Scotland may represent, not only the thin Lower Limestone shale, but also some of the older parts of the English Carboniferous Limestone.

Where typically developed, the Carboniferous Limestone is a massive well-bedded limestone, chiefly light bluish-grey in colour, varying from a compact homogeneous to a distinctly crystalline texture, and rising into ranges of hills, whence its original name "Mountain Limestone." It contains occasional scattered irregular nodules and nodular beds of dark chert. It is abundantly fossiliferous. The fossils commonly stand out on weathered surfaces of the rock, but microscopic investigation shows that even those portions of the mass which appear most structureless consist of the crowded remains of marine organisms. The limestone may be regarded as derived entirely from the organic debris of a sea-floor. Diversities of colour and lithological character occur, whereby the bedding of the thick calcareous mass can be distinctly seen. Here and there a more marked crystalline structure has been superinduced; but the most distinct examples of metamorphic change are those where the rock has been converted into what is termed "dun-stone." This alteration is frequent in the mining districts of Yorkshire and the neighbouring counties. It consists in the dolomitization of the rock along either the lines of bedding or the joints. Thus changed, it becomes a yellowish or brown crystalline dolomite, which runs vertically through the mass of the limestone along some definite joint, in courses of 20 or 30 fathoms in width. Such a metamorphism must have been effected by water percolating along the line of the joint, and affecting the rock for some distance on either side. In

Derbyshire sheets of contemporaneous lava, locally termed "troadstone," are interpolated in the Carboniferous Limestone

The fauna of the Carboniferous Limestone of England is abundant and characteristic. Numerous foraminifera occur, *Succinea*, *Carlini* being often very characteristic. The corals are numerous, including upwards of 30 genera and about 100 species. These include both simple cup corals, as *Zaphrentis*, *Cladophyllum*, and compound forms, like *Acrotelles* and *Phalliporina*. Cinnoids are individually in enormous numbers, many beds of limestone appearing to consist of little else than their fragmentary stems and cups, *Actinocrinus*, *Platycrinus*, *Paterocrinus*, *Gynothocrinus*, are common genera. Three species of sea-urchins are known. Of the trilobites, so characteristic of the older Palaeozoic rocks, the last lingering forms are here found in these small genera—*Brachymerops*, *Phallipora*, and *Griffithella*. Polyzoa abound, some portions of the limestone being almost entirely composed of them, the genera *Fenestella*, *Sulcatapora*, *Vincularia*, *Polypora*, *Diastopora*, and *Glauconema* being frequent. The brachiopods comprise 18 genera and 160 species, some of the most common forms being *Productus*, *Spirifer*, *Rhynchonella*, *Alcyon*, *Chonetes*, *Orthis*, *Lingula*, and *Discina*. But the higher mollusks now begin to preponderate over the brachiopods. The lamellibranchia number 49 genera and 334 species, including forms of *Ancillapecten*, *Leda*, *Scutella*, *Sanguinolites*, *Lepidodonta*, *Scaphites*, *Elonchidites*, *Motula*, and *Concavodonta*. The gastropods amount to 26 species belonging to 23 genera, among which *Eumphalus*, *Natica*, *Pleurotomina*, *Maccullellus*, and *Leronema* are frequent. The genus *Bellerophon* is represented by 23 species, among which *B. Urei* and *B. decussatus* are frequent. The cephalopods number 148 species, belonging among other genera to *Orthoceras*, *Nautites*, *Diceras*, and *Fenestella*. About 100 genera of fishes, chiefly from teeth and scales, have been described, as *Psephodus*, *Cochlidius*, *Cladodus*, *Petrolodus*, *Rhizodus*, *Ctenoplychius*, &c. Some of these were no doubt placoids which lived solely in the sea, but many, if not all of the ganoids, probably migrated between salt and fresh water, at least their remains are found in Scotland in strata full of land-plants, cycnids, and other indications of estuarine or fluvial conditions.

The Carboniferous Limestone series of Scotland presents a striking contrast to that of the typical formation in England. It consists mainly of sandstones, shales, fire-clays, and coal-seams, with a few comparatively thin seams of eucrinall limestone. Its lower portions include the chief limestone bands. The thickest of these seams, known as the Hurler or main limestone, is usually about 6 feet in thickness, but in the north of Ayrshire swells out to 100 feet, which is the most massive bed of limestone in any part of the Scottish Carboniferous system. It lies upon a seam of coal, and is in some places associated with pyritous shales, which have been largely worked as a source of alum. This superposition of a bed of marine limestone on a seam of coal is of frequent occurrence in the Carboniferous Limestone series of Scotland. Above the group of Lower Limestones comes a thick mass of strata containing many valuable coal-seams and ironstones. Some of these strata are full of terrestrial plants (*Lepidodendron*, *Sigillaria*, *Stigmaria*, *Sphenopteris*, *Aleiopteris*); others, particularly the ironstones, contain marine shells, such as *Lingula*, *Discina*, *Leda*, *Myalina*, *Eumphalus*. Numerous remains of fishes have been obtained, more especially from some of the ironstones and coals (*Gyracanthus formosus* and other placoid fin-spines, *Megacichthys Hübneri*, *Rhizodus Hübneri*, with species of *Elonchidites*, *Acanthodes*, *Ctenoplychius*, &c.). Remains of labyrinthodonts have also been found in this group of strata, and have been detected even down in the Bardsie House limestone. The highest division of the Carboniferous Limestone series consists of a group of sandstones and shales, with a few coal-seams, and three, sometimes more, bands of marine limestone. Although these limestones are each seldom more than 3 or 4 feet thick, they have a wonderful persistence throughout the coal-fields of central Scotland. As already mentioned, they can be traced over an area of at least 1000 square miles, and they probably extended originally over a considerably greater region. The Hurler limestone with its underlying coal can also be followed across a similar extent

of country. Hence it is evident that during certain epochs of the Carboniferous period a singular uniformity of conditions prevailed over a large region of deposit in the centre of Scotland.

The difference between the lithological characters of the Carboniferous Limestone series, in its typical development, as a great marine formation, and in its arenaceous and argillaceous prolongation into the north of England and Scotland, has long been a familiar example of the nature and application of the evidence furnished by strata as to former geographical conditions. It shows that the deeper and clearer water of the Carboniferous sea spread over the site of Yorkshire, Derbyshire, and Lancashire; that the land lay to the north; and that, while the whole area was undergoing subsidence, the maximum movement took place over the area of deeper water. It was from the northern land that the sand and mud were derived, but the sediment during the time of the Carboniferous Limestone seems to have sunk to the bottom before it could reach the great basin in which foraminifers, corals, crinoids, and mollusks were building up the great calcareous deposit. Yet the thin limestone bands, which run so persistently among the Lower Carboniferous rocks in Scotland, prove that there were occasional episodes during which the sediment ceased to arrive, and when the same species of shells, corals, and crinoids spread northwards towards the land, forming for a time over the sea-bottom a continuous sheet of calcareous ooze like that of the deeper water further south. These intervals of limestone growth no doubt point to times of more rapid submergence, perhaps also to other geographical changes whereby the sediment was for a time prevented from spreading so far.

Viewed as a whole, therefore, the Carboniferous Limestone series of Northumberland and Scotland contains the records of a long-continued but intermittent process of subsidence. The numerous coal-seams with their underclays were undoubtedly surfaces of vegetation that grew in rank luxuriance on the wide marine mud-flats, and mark pauses in the subsidence. Perhaps we may infer the relative length of these pauses by the comparative thicknesses of the coal-seams. The overlying and intervening sandstones and shales indicate a renewal of the downward movement, and the gradual infilling of the depressed area with sediment, until the water once more shoaled, and the vegetation from adjacent swamps spread over the muddy flats as before. The occasional limestones serve to indicate the epochs of more prolonged or more rapid subsidence, when marine life was enabled to flourish over the site of the submerged forests. But that the sea, even though tenanted in these northern parts by a limestone-making fauna, was not so clear and well suited for the development of animal life during some of these submergences as it was further south, seems to be proved by the paucity and dwarfed forms of the fossils in the thin limestones, as well as by the admixture of clay in the stone.

In Ireland the Carboniferous Limestone swells out to a vast thickness, and covers a large part of the island. It attains a maximum in the west and south-west, where, according to Kinahan,¹ it consists in Limerick of the following subdivisions:—

	Feet.
Upper (Barren) { Bedded limestone... ..	240
Limestone { Cherty zone... ..	20
Upper (Calp) { Limestones and shales... ..	1000
Limestone { Cherty zone... ..	40
Lower Limestone { Fenestella limestone... ..	1600
stone { Lower cherty zone... ..	20
Lower { Lower shaly limestones... ..	280
Limestone Shale... ..	100
	3600

¹ *Geology of Ireland*, p. 72.

The chert bands which form such marked horizons among these limestones are counterparts of others found abundantly in the Carboniferous Limestone of England and Scotland. They have been recently studied by Hull and Hardman, who have found them full of siliceous replacements of calcareous foraminifers, crinoids, &c., and who regard them as due to a chemical alteration on the floor of the Carboniferous sea. Portions of the limestone have a dolomitic character, and sometimes are oolitic. Great sheets of melaphyre, felsstone, and tuff, representing volcanic eruptions of contemporaneous date, are interpolated in the Carboniferous Limestone of Limerick and other parts of Ireland. As the limestone is traced northwards it shows a similar change to that which takes place in the north of England, becoming more and more split up with sandstone, shale, and coal-seams, until, at Ballycastle, it presents exactly the characters of the coal-bearing part of the formation in Scotland.

Millstone Grit.—This name is given to a group of sandstones and grits, with shales and clays, which runs persistently through the centre of the Carboniferous system from South Wales into the middle of Scotland. In South Wales it has a depth of 400 to 1000 feet, in the Bristol coal-field, of about 1200 feet. Traced northwards it is found to be intercalated with shales, fire-clays, and thin coals, and, like the lower members of the Carboniferous system, to swell out to enormous dimensions in the Pennine region. In North Staffordshire, according to Mr Hull, it attains a thickness of 4000 feet, which in Lancashire increases to 5500 feet. These massive accumulations of sediment were deposited on the north side of a barrier of Silurian and Cambrian rocks, which, during all the earlier part of the Carboniferous period, seems to have extended across central England, and which was not submerged until part of the Coal-measures had been laid down. North of this great area of deposit the Millstone Grit thins away to not more than 400 or 500 feet. It continues a comparatively insignificant formation in Scotland, attaining its greatest thickness in Lanarkshire and Stirlingshire, where it is known as the Moor Rock. In Ayrshire it does not exist, unless its place be represented by a few beds of sandstone at the base of the Coal-measures.

The Millstone Grit is generally barren of fossils. When they occur they are either plants like those in the coal-bearing strata above and below, or marine organisms of Carboniferous Limestone species. In Northumberland, indeed, it contains a band of limestone undistinguishable from some of those in the Yoredale group and Scaur limestone.

Coal-Measures.—This division of the Carboniferous system consists of numerous alternations of grey, white, yellow, sometimes reddish sandstone, dark-grey and black shales, clay-ironstones, fire-clays, and coal-seams. In South Wales it attains a maximum depth of about 12,000 feet, in the Bristol coal-field it is 5090 feet. But in these districts, as in the rest of the Carboniferous areas of Britain, we cannot be sure that all the Coal-measures originally deposited now remain, for they are always unconformably covered by later formations. In some localities, indeed, the denudation must have been very great, for the next overlying system of deposits (Permian) is found resting even on the Carboniferous Limestone. In North Staffordshire the depth of the Coal-measures is about 5000 feet, which in South Lancashire increases to 8000. These great masses of strata diminish as we trace them eastwards and northwards. In Derbyshire they are about 2500 feet thick, in Northumberland and Durham about 2000 feet, and about the same thickness on the west side of the island in the Whitehaven coal-field. In Scotland they attain a maximum of about 2000 feet.

The Coal-measures are susceptible of local subdivisions indicative of different and variable conditions of deposit. The following tables show the more important of these:—

GLANORGANSHIRE	
Upper series, more than 3400 feet	Sandstones, shales, &c., with 26 coal-seams.
Pennant Grit, 3246 feet	Hard thick-bedded sandstones &c., 15 coal-seams
Lower series, 450 to 850 feet . . .	Shales, ironstones, and 34 coal-seams.
Millstone Grit	
SOUTH LANCASHIRE.	
Upper, 1680 to 2000 feet	Shales, <i>Synoris</i> limestone, ironstone, sandstone, and thin coal-seams
Middle, 3000 to 4000.	A great series of strata, with numerous valuable coals
Lower or Gannister, 1400 to 2000 feet	Flags, shales, and three or four thin coals, with floots of "gannister"
Millstone Grit	
CENTRAL SCOTLAND	
150 feet and upwards.	Red sandstones and clays, with occasional thin coals and <i>Synoris</i> limestone.
Upwards of 2000 feet in Lanarkshire	Sandstones, shales, and fire-clays, with ironstones and coals
Moor-rock or Millstone Grit	

The numerous beds of compressed vegetation form the most remarkable feature of the Coal-measures. Each of them is usually underlain by a seam of fire-clay, representing the soil on which the plants grew. Hence they mark successive terrestrial surfaces, which, after enduring for a longer or shorter period, were carried down beneath the water and covered over with sand and silt. There is no modern formation that affords a close parallel to that of the ancient coal-growths. The nearest analogy is furnished by the mangrove swamps alluded to already on p. 290. These masses of arborescent vegetation grow out into the sea as a belt or fringe on low shores, and form a matted soil which adds to the breadth of the land. Their roots spread in the salt water where marine organisms are abundant. The coal-growths no doubt also flourished in salt or at least brackish water, for such shells as *Avicula pecten*, *Anthracosia*, and *Goniatites* are found lying on the coal or in the shales attached to it.

The vegetation of the Carboniferous period must have been luxuriant and varied. Upwards of 500 species of plants have been obtained from the Carboniferous rocks of Britain, yet these must represent but a small portion of the original flora.

The most abundant forms were ferns and lycopods. Numerous root-like plants likewise played a conspicuous part in the general vegetation of the low grounds, while apparently on the drier and more elevated tracts (for their remains are less frequently met with) large coniferous trees flourished. The ferns strikingly resemble many modern forms. Among the more frequent genera were *Sphenopteris*, *Pecopteris*, *Alethopteris*, *Neuropteris*, and *Cyclopteris*. The lycopodiaceous plants attained the size of forest trees. Among the most typical forms were many species of *Lepidodendron*, the stems and seed-cones of which are scattered through the Carboniferous strata. Some of the coal-seams are largely composed of the spores of these plants. *Sigillaria*, regarded by some as allied to the cycads, by others as more akin to the lycopods, is represented by numerous species. The roots known as *Sigillaria* are abundant in most fire-clays, showing how largely the coal consists of trees having roots of this kind. The *Equisetaceae* show themselves in the form of numerous *Calamites* which, though resembling in general aspect our modern horse-tails, differed in many points of structure, and notably in their gigantic size. Coniferous trees occur chiefly in the form of stems and branches. They include the genera *Dacrydium*, *Aracium*, *Weylandia*, and *Pinites*. Small nut-like fruits (*Trigonocarpium*) abound in some beds, and are now believed to be the fruits of yew-like conifers. The presence of monocotyledonous plants is proved by the *Pothoites* referred to above (p. 347).

The animal remains of the Coal-measures are comparatively few. In certain bands, particularly of ironstone, numerous mollusca occur, and similar forms are to be occasionally met with in the shales.

Among the more frequent species are *Anthracocya nodulosa*, *Anthracocya ovalis*, *A. robusta*, *A. acuta*, *Anthracocya Brouniana*, *Aneuroleptus pygæus*, and *Goniatites Listeri*. But at the top of the Middle Coal-measures, near Manchester, a band of true marine shells occurs, including *Cleatodonta*, *Nautilus*, *Discus*, *Goniatites*, and *Orthoceras*. The little *Spirifer carboarius* is abundant in some shales. The crustaceans are chiefly represented by *Bygonia* and frequently, remains of the large kinds usually appearing as scales, teeth, fin-spines, or bones, while the smaller goniatites often preserve entire. Common species are *Aegialithus Hibberti* (?), *Rhynchus granulatus*, *Calacanthus lrytus*, *Palaemonites Egertoni*, *Pleuroacanthus gibbosus*. The British Carboniferous rocks have yielded 13 genera of labyrinthodonts (*Lithacanthus*, *Loxonotus*, *Amblopteron*, *Pholidopteron*, *Pteropelyx*, *Urocyonotus*, &c.). These were probably fluvial animals of predaceous habits, living on fish, crustacea, and other organisms of the fresh or salt waters of the coal lagoons. The larger forms are believed to have measured 7 or 8 feet in length, some of the smaller examples, though adult and perfect, do not exceed as many inches.¹ That the woods of the Carboniferous period were not devoid of insect life is known from the discovery of some beetles and neuropteræ at Coalbrookdale.

CONTINENTAL EUROPE.—As in Britain so on the Continent the Carboniferous system occupies many detached areas or basins—the result partly of original deposition, partly of denudation, and partly of the spread and overlap of more recent formations. There can be no doubt that the English Carboniferous Limestone once extended continuously eastward across the north of France, along the base of the Ardennes, through Belgium, and across the present valley of the Rhine into Westphalia. From the western headlands of Ireland this calcareous formation can thus be traced eastward for a distance of 750 English miles into the heart of Europe. It then begins to pass into a series of shales and sandstones, which no doubt represent the same proximity to shore as the similar strata in the north of England and Scotland. In Silesia, and still much farther eastwards in central and southern Russia, representatives of the Carboniferous Limestone appear, but interstratified, as in Scotland, with coal-bearing strata. Traces of the same blending of marine and terrestrial conditions are found also in the north of Spain. But over central France, and eastwards through Bohemia and Moravia into the region of the Carpathians, the Coal-measures rest directly upon the older formations, most commonly upon gneiss and other crystalline rocks. It would appear that these tracts had remained above water during the time of the Carboniferous Limestone, but were gradually depressed during that of the Coal-measures.

In the north of France and Belgium the British type of the Carboniferous system is well shown. At the base lies a group of green, grey, and reddish shales and yellow sandstones, precisely similar in lithological character to parts of the Calcareous Sandstones of Scotland. They are well seen in some recent railway cuttings to the north of Boulogne, and also in the valley of the Meuse above Namur, lying upon the *Psammites* of Condor or Upper Devonian beds. They are succeeded by the Carboniferous Limestone, which is subdivided into eight formations, having an aggregate thickness of 800 metres, and each characterized by its own assemblage of fossils. The horizon of the Millstone Grit is marked by the occurrence of certain alumn-schists. The Coal-measures of this area have been referred to in the article COAL.²

The Starbrück coal-field furnishes a good example of that type of the Carboniferous system where the lower marine series is absent. It lies unconformably on Devonian rocks, and attains a thickness

of more than 10,000 feet. It is divided into the following groups of strata.—

- 2 Upper series, consisting at the top of red sandstones, below which come shales, sandstones, &c., with a few coal-seams—*Anthracocya*, *Eskia*

- 1 Lower series, consisting of an upper group of red conglomerates, sandstones, clays, resting upon the great coal-bearing division. Abundant plants, with labyrinthodonts and insect remains.

Gemtz, drawing attention to the distribution of plants in the Saxon Coal-measures, remarks that a certain order can be observed in their appearance. He divides the strata accordingly into three zones, each marked by a characteristic assemblage of plants, and he believes that the classification can be applied in other countries.

- 3 The Fern Zone, marked by the profusion of its ferns (*Sphenopteris*, *Hyponeurophyllites*, *Schizopteris*, *Odonopteris*, *Neuropteris*, *Cyclopteris*, *Atelopteris*, *Caulopteris*) This is underlain by

- 2 The Sigillaria Zone, containing many species of *Sigillaria* (also *Lepidodendron*, *Calamites*, *Asterophyllites*, and a few ferns

1. The Lycopod Zone, abounding in *Sageneia*, *Vettheimania*, with *Sphenopteris distans*, *Calamites transiensis*, &c.

The lowest of these zones (1) is computed by Gemtz with the Culm, that is, the sandy, shaly, and coal-bearing representative of the Carboniferous Limestone. To the east of the Rhine valley, as already mentioned, the true Carboniferous Limestone loses its normal character and assumes that of the Culm—a series of shales, sandstones, greywackes, and conglomerates, in which the abundant fauna of the limestone is reduced to a few mollusks (*Produnctus antiquus*, *P. latissimus*, *P. semibicinctatus*, *Posidonomya Beheri*, *Goniatites sphericus*, *Orthoceras striatulum*, &c.). The *Posidonomya* particularly characterizes certain dark shales known as *Posidoniaschists*. About 60 species of plants have been obtained from the Culm, typical species being *Calamites transiensis*, *Sageneia Vettheimania*, *Stigmaria florides*, *Sphenopteris distans*, *Cyclopteris tenuifolia*. This flora bears a strong resemblance to that of the Calcareous Sandstones of Scotland.

NORTH AMERICA.—Rocks corresponding in geological position and the general aspect of their organic contents with the Carboniferous system of Europe are said to cover an area of more than 200,000 square miles in the United States and British North America. The following table shows the subdivisions which have been established among them :—

Carboniferous	Coal-measures, —a series of sandstones, shales, ironstone, coals, &c., varying from 100 feet in the interior continental area to 4000 feet in Pennsylvania, and more than 8000 feet in Nova Scotia. The plant remains include forms of <i>Lepidodendron</i> , <i>Sigillaria</i> , <i>Stigmaria</i> , <i>Calamites</i> , ferns, and coniferous leaves and fruits. The animal forms embrace in the numerous bands species of <i>Spirifer</i> , <i>Protospira</i> , <i>Dellerella</i> , <i>Nautilus</i> , &c. Among the shales and conglomerates beds numerous traces of insect life have been obtained, comprising species related to the may-fly and cockroach. Spiders, scorpions, centipedes, limuloid crabs, and land snails like the modern <i>Pupa</i> have also been met with. The fish remains comprise teeth and ichthyodonts of placoid genera, and a number of ganoids (<i>Eurypterus</i> , <i>Calceuranthus</i> , <i>Megalichthys</i> , <i>Rhacodus</i> , &c.) Several labyrinthodonts occur, and true reptiles are represented by one samian genus found in Nova Scotia, the <i>Eosaurus</i> .
	Millstone Grit, —a group of arenaceous and sometimes conglomeratic strata, with occasional coal-seams, only 25 feet thick in some parts of New York, but swelling out to 1500 feet in Pennsylvania.
	Chester group —Limestones, shales, and sandstones, sometimes 600 feet.
	St Louis group —Limestones with shale, in places 250 feet.
	Kookuk group —Limestone with chert layers and nodules.
Sub-Carboniferous	Burlington group —Limestone, in places with chert and hornstone, 25 to 200 feet.
	Kinderhook group —Sandstones, shales, and thin limestones, 100 to 200 feet, resting on the Devonian black shale.
	The sub-Carboniferous groups are mainly marine limestones, but contain here and there remains of the characteristic Carboniferous land vegetation. Crinoids of many forms abound in the limestones. A remarkable polyzoan, <i>Archimedes</i> , occurs in some of the bands. The brachiopods are chiefly represented by species of <i>Spirifer</i> and <i>Produnctus</i> ; the lamellibranchs by <i>Schizophoria</i> , <i>Strophodontes</i> , <i>Navalis</i> , <i>Pinnis</i> , and others; the cephalopods by <i>Orthoceras</i> , <i>Nautilus</i> , <i>Goniatites</i> , <i>Eurypterus</i> , &c. The European genus of trilobite, <i>Phylloporus</i> , occurs. Numerous teeth and fin-spines of selachian fishes give a further point of resemblance to the European Carboniferous Limestone. Some of the ripple rain-pitted beds contain amphibian foot-prints—the earliest American forms yet known.

¹ Mall, *Brit. Assoc. Rep.*, 1873, p. 946.

² On the article COAL, vol. vi. p. 66, the coal basin of Harbington is said to be of Carboniferous Limestone age. This, which appeared to be the most probable view of a very obscure point, has been proved to be a mistake, as the strata are actually Coal-measures in every position, the same disturbance being characteristic of the south side of the basin of the Thra-Caine for a considerable distance. This is now so generally recognized that belief for coal in that basin through the *Trenton* and *Onondaga* formations are not necessarily stopped on reaching Devonian strata, as coal-seams have been discovered vertically below the older strata at considerable depths, e.g. at Inchy in Iowa. In another pt. at *Concord*, the fact that the limestones on the upper levels are inverted in position has been recently proved by the sinking, traversing the same seams in reverse order, i.e. in their normal position. This discovery is of the highest importance bearing on the question of the probable extension of the Coal-measures in the south-east of England. The discovery (in 1878) of Devonian strata at the moderate depth of 1400 feet in the *Massena* of *Massena* is a very interesting fact that bears out the views previously put forward by H. Goudin in Austria.

PERMIAN.

BRITAIN.—In England the Coal-measures are unconformably overlaid by a series of red sandstones, conglomerates, breccias, and marls, which at one time were grouped in one great formation as the New Red Sandstone, in contradistinction to the *Old Red Sandstone* lying below the Carboniferous system. They were likewise known as the *Poikilitic series*, from their mottled or variegated colours. They are now divided into two systems or groups of formations, the lower half being included in the *Palæozoic series* under the name of *Permian* (after *Perm*, a Russian province where they are well displayed), and the upper half being relegated to the *Secondary series*, and termed *Trias*.

The Permian system in England consists of the following subdivisions:—

		W of England	E of England
3 Upper	Red sandstones, clays, and gypsum	600 ft	50-100 ft
2 Middle	Magnesian limestone Mall slate	10-30 "	600 "
1 Lower	Red and variegated sandstone Reddish-brown and purple sandstones and marls, with calcareous conglomerates and breccias of volcanic rocks	3000 "	100-250 "

From the thicknesses here given, it is evident that the Permian rocks have a very different development on the two sides of England. On the east side, from the coast of Northumberland southwards to the plains of the Trent, they consist chiefly of a great central mass of limestone. But on the west side of the Pennine Chain, and extending southwards into the central counties, the calcareous zone disappears, and we have a great accumulation of red, arenaceous, and gravelly rocks.

Lower.—This subdivision attains its greatest development in the vale of the Eden, where it consists of brick-red sandstones, with some beds of calcareous conglomerate or breccia, locally known as "brockram," derived from the waste of the Carboniferous Limestone. These red rocks extend across the Solway into the valleys of the Nith and Annan, in the south of Scotland, where they lie unconformably on the Lower Silurian rocks. Their breccias consist of fragments of the adjacent Silurian greywackes and shales, but near Dumfries some calcareous breccias or "brockrams" occur. These brecciated masses have evidently accumulated in small lakes or narrow fjords. Much further south, in Staffordshire, and in the districts of the Clent and Abberley Hills, the brecciated conglomerates in the Permian series attain a thickness of 400 feet. They have been shown by Ramsay to consist in large measure of volcanic rocks, grits, slates, and limestones, which can be identified with rocks on the borders of Wales. Some of the stones are 3 feet in diameter and show distinct stration. The same writer has pointed out that these Permian drift-beds cannot be distinguished by any essential character from modern glacial drifts, and he has no doubt that they were ice-borne, and, consequently, that there was a glacial period during the accumulation of the Lower Permian deposits of the centre of England.

Like red rocks in general the Lower Permian beds are almost barren of organic remains. Such as occur are indicative chiefly of terrestrial surfaces. Plant remains occasionally appear, such as *Caulerpites* (supposed to be of marine growth), *Lepidodendron dilatatum*, *Calamites*, *Sternbergia*, and fragments of coniferous wood. The cranium of a labyrinthodont (*Dasypeps*) has been obtained from the Lower Permian rocks at Kenilworth. Footprints referred to members of the same extinct order have been observed abundantly on the surfaces of the sandstones of Dumfries-shire, and also in the vale of the Eden.

Middle.—This subdivision is the chief repository of fossils in the Permian system. Its strata are not red,

but consist of a lower zone of hard brown shale with occasional thin limestone bands (Mall Slate) and an upper thick mass of dolomite (Magnesian Limestone). The latter is the chief feature in the Permian development of the east of England. It corresponds with the *Zechstein* of Germany, as the *Mall Slate* does with the *Kupfer-schiefer*. It is a very variable rock in its lithological characters, being sometimes dull, earthy, fine-grained, and fossiliferous, in other places quite crystalline, and composed of globular, reniform, botryoidal, or other irregular concretions of crystalline and frequently internally radiated dolomite. Though the Magnesian Limestone runs as a thick persistent zone down the east of England it is represented on the Lancashire and Cheshire side by bright red and variegated sandstone covered by a thin group of red marls, with numerous thin courses of limestone, containing *Schizodus*, *Bakewellia*, and other characteristic fossils of the Magnesian Limestone.

The middle Permian division has yielded about 100 species belonging to 46 genera of fossils—a singularly poor fauna when contrasted with that of the Carboniferous system below. The brachiopods (9 genera, 21 species) include *Productus horridus*, *Camarophoria multiplicata*, *C. Schlotheimi*, *Strophalosia Goldfussi*, *Lingula Caledoniæ*, and *Teretabula elongata*. The lamellibranchs number 16 genera and 31 species, among which *Schizodus Schlotheimi*, *Bakewellia tremula*, *B. enigma*, *B. ceratophaga*, *Mytilus symmorus*, and *Levæstrotia* are characteristic. The univalves are represented by 11 genera and 26 species, including *Pleurodonaria* and *Turbo* as common genera. Fishes have been obtained chiefly in the mall slate to the number of 21 species belonging to 8 genera, of which *Palaoniscus* is the chief. These small ganoids are closely related to some which haunted the lagoons of the Carboniferous period.

Upper.—Murchison and Harkness have classed as Upper Permian certain red sandstones with thin partings of red shale, and an underlying band of red and green marls and gypsum. These rocks, seen at St Bees, near Whitehaven, resting on a magnesian limestone, have not yet yielded any fossils.

CONTINENTAL EUROPE.—The two types of the Permian system presented by the east and west sides of England (appearing in different areas on the mainland of Europe). The eastern or Durham type is found in enormous masses of strata flanking the Harz Mountains, also in Thuringia, in Saxony, and in Bohemia. The western or Salopian type is found over many thousands of square miles in the north and east of Russia.

The German geologists, recognizing the remarkable twofold character of its rocks, have called this system "Dyas," and have proposed to retain the term Permian to express the more simple type, such as is found in Russia and western England. They group the members of their Dyas as follows:—

Zeelandian Group.	Anhydrite, gypsum, rock-salt, marl, dolomite, fossil shale and limestone. The amorphous gypsum is the chief member of this group; the limestone is sometimes full of bitumen
	Crystalline granular (<i>Zauchkeace</i>) and fine sandy (<i>Asche</i>) dolomite (6 to 95 feet)
Rothliegendes Group.	Zechstein, an argillaceous thin-bedded compact limestone 15 to 30 (sometimes even 90) feet thick
	Kupfer-schiefer—a black bituminous shale not more than about 2 feet thick
	Zechstein, conglomerate, and calcareous sandstone
	Upper—Conglomerates (quartz-porphry conglomerate) and sandstone, with associated melaphyres and tufts.
	Middle—Red clays, shales, and fine shaly sandstones, with bands of quartz-conglomerates and earthy limestone. Melaphyre and porphyrite masses intercalated
	Lower—Shaly sandstones, shales (with bituminous bands), and conglomerates

The name "Rothliegendes" or "Rothtoddiegendes" (red-layer or red-dead-layer) was given by the miners because their ores disappeared in the red rocks below the copper-bearing Kupfer-schiefer. The coarse conglomerates have been referred by Ramsay to a glacial origin, like those of the Abberley Hills. One of the most interesting features of the formation is the evidence of the contemporaneous

outpoing of great sheets of quartz-porphry, granite-porphry, porphyrite, and melaphyre, with abundant interstratifications of various tuffs, not unfrequently enclosing organic remains. From the very nature of its component materials, the Rothliegendes is comparatively barren of fossils, a few ferns, calamites, and remains of coniferous trees are found in it, particularly towards the base, where indeed they form, in the Mansfield district, a coal-seam about 5 feet thick.

The plants, all of terrestrial growth, on the whole resemble generically the Carboniferous flora, but seem to be nearly all specifically distinct. They include forms of *Calamites* (*C. gigas*), *Asterophyllites*, and ferns of the genera *Sphenopteris*, *Allophloia*, *Neuropteris*, *Odontopteris*, with well-preserved silicified stems of tree-ferns (*Pecopteris*, *Trichopteris*). The conifer *Waldius* (*W. piniformis*) is specially characteristic. Fish remains occur sparingly (*Ichthyosaurus*, *Palaemoniscus*, *Acanthopterus*), and traces of labyrinthodonts (*A. chestonii* or *Zecheni*) have been met with.

The Zechstein group is characterized by a suite of fossils like those of the Middle Permian of England. The Kupfer-schiefer contains numerous fish (*Palaemoniscus Fossilensis*, *Platysomus gibbosus*, &c.) and remains of plants (coniferous leaves and fruits and sea-needs). This deposit is believed to have been laid down in some enclosed sea-basin, the waters of which, probably from the use of mineral springs connected with some of the volcanic foci of the time, were so charged with metallic salts in solution as to become unfit for the continued existence of animal life. The dead fish, plants, &c., by their decay, gave rise to reduction and precipitation of these salts as sulphides, which thereupon enclosed and replaced the organic forms, and permeated the mud at the bottom. This old sea-floor is now the widely extended band of copper-slate which has so long and so extensively been worked along the flanks of the Harz. After the formation of the Kupfer-schiefer the area must have been once more covered by clear water, for the Zechstein contains a number of organisms of which *Prodolodus hornatus*, *Spinifer undulatus*, *Strophodonta Golfussii*, *Schizodus elegans*, and *Psacodius retiformis* are common. Renewed unfavourable conditions are indicated by the dolomite, gypsum, and rock-salt which succeed. Professor Ramsay, reasoning upon such phenomena as developed in England, has connected them with the abundant labyrinthodont footprints and other evidences of shores and land, as well as the small number and dwarfed forms of the shells in the Magnesian Limestone, and has speculated on the occurrence of a long continental period in Europe, during one epoch of which a number of salt inland seas existed wherein the Permian rocks were accumulated. He compares these deposits to what may be supposed to be forming now in parts of the Caspian Sea.

NORTH AMERICA.—The Permian system is hardly represented at all in this part of the globe. In Kansas certain red and green clays, sandstones, limestones, conglomerates, and beds of gypsum lie conformably on the Carboniferous system, and contain a few genera and species of molluscs (*Dakewella*, *Nyalna*, &c.), which occur in the European Permian rocks.

III. SECONDARY OR MESOZOIC

TRIASSIC

It has been already mentioned that the great mass of red rocks, which in England overlie the Carboniferous system, were formerly classed together as New Red Sandstone, but are now ranged in two systems. We have considered the lower of these under the name of Permian. The general facies of organic remains in that division is still decidedly Paleozoic. Its brachiopods and its plants connect it with the Carboniferous rocks below. Hence it is placed at the close of the long series of Paleozoic formations. When, however, we enter the upper division of the red rocks, though the general lithological characters remain very much as in the lower group, the fossils bring before us the advent of the great Mesozoic flora and fauna. This group therefore is put at the base of the Mesozoic or Secondary series. It is called Trias, because in Germany it consists of three well-marked subdivisions. But the old name, New Red Sandstone, is familiarly retained for it by many geologists in England. The term Trias, like Dyas, is unfortunately chosen, for it elevates a mere local character into an importance which it does not deserve. The threefold subdivision, though so distinct in Germany, disappears elsewhere.

GREAT BRITAIN.—Triassic rocks occupy a large area of

the low plains in the centre of England, ranging thence northwards along the flanks of the Carboniferous tracts to Lancaster Bay, and southwards by the head of the Bristol Channel to the south-east coast of Devonshire. They have been arranged in the following subdivisions:—

Rhætic .	{ Pennine beds—Red, green, and grey marls, and "White Lias"
Upper Trias or Keuper	{ New Red Marl—Red and grey shales and marls, with beds of rock-salt and gypsum (<i>Estlinia</i> and <i>Zooceras</i> forms) Lower Keuper Sandstone—Thinly laminated micaceous sandstones and marls (waterstones) passing downwards into white, brown, or reddish sandstones, with a base of calcareous conglomerate or breccia
Middle	{ Wanting in England (Muschelkalk of Germany). Upper Mottled Sandstone—Soft bright-red and variegated sandstones, without pebbles
Lower Trias or Bunter	{ Pebble beds.—Harder reddish-brown sandstones with quartz pebbles, passing into conglomerate, with a base of calcareous breccia Lower Mottled Sandstone—Soft bright-red and variegated sandstone, without pebbles

Like the Permian red rocks below, the sandstones and marls of the Triassic series are almost barren of organic remains. Hence the subdivisions in the foregoing table are based on mineral characters, and could not therefore be relied on as a guide in districts outside of the English area. Indeed, extraordinary differences in the development of the different members of the series occur, even within that area, as may be seen from the subjoined table, which shows the variations in thickness from north-west to south-east—

	Lancashire and W. Cheshire	Staffordshire	Leicestershire and Warwickshire
Keuper.	Feet 8000 450 500	Feet 800 200 50-200	Feet 700 150 absent
Bunter	Feet 650-750 200-500	Feet 100-300 0-100	Feet absent absent

Hence we observe that, while towards the north-west the Triassic rocks attain a maximum depth of 5200 feet, they rapidly come down to a fifth or a sixth of that thickness as they pass towards the south-east. Recent borings in the south-eastern counties show that the Triassic rocks are there absent altogether. It is evident that the source of supply of the sediment lay towards the north. This is further borne out by the character of the pebble-beds. These are coarsest towards the north, and, besides local materials, contain abundant rolled pebbles of quartz which have evidently been derived from some previous conglomerate, probably from some of the Old Red Sandstone masses now removed or concealed. The Trias everywhere rests unconformably on the rocks underneath it, so that, although the general physical conditions as regards climate, geography, and sedimentation, which prevailed in the Permian period still continued, great terrestrial movements had, in the meanwhile, taken place, whereby the Permian sediments were upraised and exposed to denudation. Hence the Trias rests now on Permian, now on Carboniferous, and sometimes even on Cambrian rocks. Moreover, the upper parts of the Triassic series overlap the lower, so that the Keuper groups come to rest directly on Permian or Carboniferous rocks.

One of the most interesting features in the English Trias is the occurrence of beds of rock-salt which have long been profitably worked. The uppermost subdivision of the Keuper, consisting of red marls, has a wide distribution, for it can be traced from the coast of Lancashire to the Bristol Channel, and covers a larger area of surface in the central counties than the rest of the Trias and the whole of the Permian sandstones combined. Even as far south as the

coast of Devonshire, it contains casts of the cubical spaces once occupied by crystals of common salt. But in Cheshire the salt occurs in two or more beds, of which the lower is sometimes upwards of 100 feet thick. It is a crystalline substance, usually tinged yellow or red from intermixture of clay and peroxide of iron, but is tolerably pure in the best part of the beds, where the proportion of chloride of sodium is as much as 98 per cent. Through the bright red marls with which the salt is interstratified there run bands of gypsum, somewhat irregular in their mode of occurrence, sometimes reaching a thickness of 40 feet and upwards. Thin seams of rock-salt likewise occur among the red marls. These facts point to the concentration and evaporation of salt lakes or inland seas.

The organic remains of the Trias are comparatively few, as the conditions for at least animal life must have been extremely unfavourable in the waters of the ancient Dead Sea wherein these red rocks were accumulated. The land possessed a vegetation which, from the few fragments yet known, seems to have consisted in large measure of cypress-like coniferous trees (*Folium, Walckena*), with calamites on the lower more marshy grounds. The red marl group contains in some of its layers numerous valves of the little custacean *Eothieria murata*, and a solitary species of lamellicorn, *Pullastra arenicola*. A number of teeth, spines, and sometimes entire skeletons of fish have been obtained (*Diplacodonus cyphus*, *Palaeoniscus superstes*, *Hybodus Keuperi*, *Acerodus minimus*, *Sphenonchus minimus*, *Lophodus*, &c.). The bones, and still more frequently the footprints, of labyrinthodonts and even of saurian reptiles occur in the Keuper beds—*Labyrinthodon* (4 species), *Cleidydon*, *Lladys*, *Hyperolapodon*, *Palaeosaurus*, *Tetrasaurus*, *Thecodontosaurus*, *Rhynchosaurus*, and footprints of *Cheylitherium*. The remains of a small marsupial (*Microlestes*) have likewise been discovered.

Rhætic.—At the top of the Red Marl certain thin-bedded strata form a gradation upwards into the base of the Jurassic system. As their colours are grey and blue, and contrast with the red marls on which they repose conformably, they were formerly classed without hesitation in the Jurassic series. Egerton, however, showed that, from the character of their included fish remains, they had more palaeontological affinity with the Trias than with the Lias. Subsequent research, particularly among the Rhætic Alps and elsewhere on the Continent, brought to light a great series of strata of intermediate characters between the Trias and Lias. These results led to renewed examination of the so-called beds of passage in England, which were found to be truly representative of the massive formations of the Tyrol and Swiss Alps. They are therefore now classed as Rhætic, and considered as the uppermost member of the Trias, but offering evidence of the gradual approach of the physical geography and characteristic fauna and flora of the Jurassic period.

The Rhætic beds extend as a continuous though very thin band at the top of the Trias, from the coast of Yorkshire across England to Lyme Regis on the Dorsetshire shores. They occur in scattered patches even up as far as Carlisle, and westwards on both sides of the Bristol Channel. Their thickness, on the average, is probably not more than 50 feet, though it rarely increases to 150 feet. They consist of thin-bedded grey and dark shales and clays, with bands of light-coloured limestone. One of their most important subdivisions is the so-called Bone-bed—a pyritic, micaceous, and occasionally rippled sandstone, sometimes in several bands, abounding in fish bones, teeth, coprolites, and other organic remains. The grey marly beds in the lower portion of the series have yielded remains of the *Microlestes Rhæticus*. Among the reptilian fossils are some precursors of the great forms which distinguished the Jurassic period (*Ichthyosaurus* and *Plesiosaurus*). The fishes include *Acerodus minimus*, *Ceratodus altus*, *Hybodus minor*, *Nemacanthus monstifer*, &c. Some of the lamellicornians are specially characteristic; such are *Cardium Rhæticum*, *Avicula contorta*, *Pecten Palæoniscus*, and *Pullastra arenicola*.

Professor Renssler has drawn attention to the probable geographical changes recorded by the Triassic rocks of England. Connecting them with the earlier and similar Permian sandstones and marls he points out that the great Continental period which began with the Old Red Sandstone closed with the New Red Marl, and was characterized by the existence of great lakes, many of which must have been salt, and by the abundance of labyrinthodont

life. The Triassic rocks were, doubtless, laid down in one of these salt lakes round the margins of which the labyrinthodonts left their footprints on the soft sand. In the Rhætic series we see how these inland basins were gradually invaded by the sea, which brought into the region of Britain the rich fauna of the Jurassic period.

CONTINENTAL EUROPE.—The Trias is the most compactly distributed of all the geological formations of Europe. Its main area extends as a great basin from Basel down to the plains of Hanover, traversed along its centre by the course of the Rhine, and stretching from the flanks of the old high grounds of Saxony and Bohemia on the east across the Vosges mountains into France. This must have been a great inland sea, out of which the Harz mountains, and the high grounds of the Eifel, Hunsrück, and Taunus probably rose as islands. It may have extended up to the base of the Alps, for enormous masses of Triassic rocks now form part of these mountains. Traces of what were probably other basins occur eastward in the Carpathian district, along the southern front of the Alps, in the west and south of France, and over the eastern half of the Spanish peninsula. But these areas have been considerably obscured, sometimes by dislocation and denudation, sometimes by the overlap of more recent formations.

In the great German Triassic basin the deposits are as shown in the subjoined table.

Kauper	Upper or Rhætic.—Grey sandy clays and fine-grained sandstones, containing <i>Equisetum</i> , <i>Azolenites</i> , and <i>Cyrtos</i> (<i>Zamites</i> , <i>Pterophyllum</i>), sometimes forming thin seams of coal— <i>Cardium Rhæticum</i> , <i>Avicula contorta</i> , <i>Eothieria murata</i> , <i>Nehosaurus</i> , <i>Tetrasaurus</i> , <i>Belodon</i> , and <i>Alto olesites antiquus</i> .
	Middle (Bunte Keupermergel, Gypskeuper).—Bright red and mottled marls, with beds of gypsum and rock-salt. In some places where sandstones appear they contain numerous plants (<i>Equisetum columnare</i> , <i>Taxiopteris ovata</i> , <i>Pterophyllum</i> , &c.), and labyrinthodont and fish remains. 300 to 1000 feet.
	Lower (Lettenkohle, Kohlenkeuper).—Grey sandstones and dark marls and clays, with abundant plants, sometimes forming thin seams of an earthy highly workable coal (Lettenkohle). The plants include, besides those above mentioned, the conifers <i>Aracoezylon Thuringicum</i> , <i>Folcia heterophylla</i> , &c. Some of the shales are crowded with small ostracod crustaceans (<i>Eothieria murata</i>). Remains of fish (<i>Ceratodus</i>) and of the <i>Alatodactylus Jegeri</i> have been obtained. About 250 feet.
Muschelkalk	Upper Limestone in thick beds with argillaceous partings.—It abounds in organic remains among which <i>Ceratodus nodosus</i> , <i>Nautilus induratus</i> , <i>Lima striata</i> , <i>Myophoria vulgaris</i> , <i>Trogonodus Sandbergeri</i> , <i>Terebratula vulgaris</i> , and <i>Zenocrinus liliiformis</i> are specially characteristic. It is a thoroughly marine formation, sometimes almost wholly made up of crinoid stems. 200 to 400 feet.
	Middle Limestone and Anhydrite, consisting of dolomites with anhydrite, gypsum, and rock-salt. Nearly devoid of organic remains, though bones and teeth of saurians have been found. 200 to 400 feet.
	Lower Limestone, consisting of limestones and dolomites, but on the whole poor in fossils, save in the limestone bands, some of which are full of <i>Terebratula vulgaris</i> and <i>Zenocrinus liliiformis</i> . 160 to 500 feet.
	Upper (Roth).—Red and green marls, with gypsum in the lower part. 250 to 300 feet.
Bunter	Middle.—Coarse-grained sandstones, sometimes incoherent, with waybeds of <i>Eothieria</i> shale.
	Lower.—Fine reddish argillaceous sandstone, often micaceous and fissile, with occasional interstratifications of dolomite and of the marly oolitic limestone called "Rogenstein." The Bunter division is usually barren of organic remains. The plants already known include <i>Equisetum arvense</i> , one or two ferns, and a few conifers (<i>Albetrus</i> and <i>Folcia</i>). The lamellicorn <i>Myophoria costata</i> is found in the upper division all over Germany. Numerous footprints occur on the sandstones, and the bones of labyrinthodonts as well as of fish have been obtained.

The Trias attains an enormous development in the eastern Alps, where it bears evidence of having been accumulated under very different conditions from those of the Trias in Germany. The great thickness of its limestones, and their unequivocally marine organisms, show that it must have accumulated in open water, which remained clear and comparatively free from inroads of sandy and muddy sediment. It possesses, moreover, a high interest as being a massive formation of marine origin formed between Permian

and Jurassic times, and containing a remarkable blending of true Paleozoic organisms with others as characteristically Mesozoic. It is divided into two great series.—(1) Lower Trias, consisting of (a) Werfen Shales and Guttenstein Limestone, and (b) Virgilia Limestone or alpine Muschelkalk; and (2) Upper Trias,—a varied series of strata in three leading groups, having a united thickness sometimes of thousands of feet.

NORTH AMERICA.—Rocks which are regarded as equivalent to the European Trias cover a large area in North America. On the Atlantic coast they are found on Prince Edward's Island, New Brunswick, and Nova Scotia, in Connecticut, New York, Pennsylvania, and North Carolina. Spreading over an enormous extent of the western territories, they cross the Rocky Mountains into California and British Columbia. They consist mainly of red sandstones, passing sometimes into conglomerates, and often including shales and impure limestones. On the Pacific slope they contain distinctly marine organisms, which include a mingling of such Paleozoic genera as *Spinifer*, *Orthis*, and *Goniolites*, with the characteristically Secondary genus *Ammonites*. In the centre and east of the continent they are marked by the occurrence of terrestrial plants, and in Connecticut by abundant footprints of land animals. The fossil plants present a general facies like that of the European Triassic flora, among them cycads, including some of the European species of *Pterophyllum*. Ferns (*Pecopteris*, *Neuropteris*, *Clathropteris*), calamites, and conifers are the predominant forms. The fauna is remarkable chiefly for the number and variety of its vertebrates. The labyrinthodonts are represented by footprints, from which upwards of fifty species have been described. Saurian footprints have likewise been recognized, but in a few cases their bones also have been found. These saurians had some bird-like characteristics, among others that of three-toed hind feet, which produced impressions exactly like those of birds. It is by no means certain, therefore, that what have been described as ornithomimids were not really made by dinosaurs. A small insectivorous marsupial (*Dromatherium*), found in the Trias of North Carolina, is the oldest American mammal yet known.

JURASSIC.

The next great period of geological time is termed the Jurassic, from the Jura Mountains, where the deposits of that age are well developed. It was in England, however, that they were first studied by William Smith, in whose hands they were made to lay the foundations of stratigraphical geology. The names adopted by him for the subdivisions he traced across the country have passed into universal use, and though some of them are unorthodox English provincial names, they are as familiar to the geologists of France, Switzerland, and Germany as to those of England.

The Jurassic formations stretch across England in a varying band from the mouth of the Tees to the coast of Dorsetshire. They consist of harder sandstones and limestones interstratified with softer clays and shales. Hence they give rise to a characteristic type of scenery,—the more durable beds standing out as long ridges, sometimes even with low cliffs, while the clays underlie the level spaces between. Arranged in descending order, the following subdivisions of the English Jurassic system are recognized:—

		Maximum thickness. Feet.
Upper or Portland Oolites.	Purbeck. { Upper fresh-water beds	360
	{ Middle marine beds	
	{ Lower fresh-water beds	70
	Portland. { Portland Stone	150
	{ Portland Sand	600
Audford or Oxford Oolites.	Coralline Oolite. { Coral Rag and Calcareous Grit	250
	{ Oxford Clay and Kellaways Rock	600

		Maximum thickness. Feet.
Lower or Bath Oolites.	Great Oolite. { Cornbrash, Bradford Clay and Forest Marble (in Dorsetshire 450 ft.)	40
	{ Great or Bath Oolite with Stonesfield slates (part of Northampton Sand)	130
	Fuller's Bath. { Fuller's Earth group	150
	{ Cheltenham beds	270
	Inferior Oolite. { Midford Sands (and perhaps part of Northampton Sands), "Dogger" of Yorkshire	160
Lias.	Upper Lias	400
	Marlstone	200
	Lower Lias	900

Although these names appear in tabular order as expressive of what is the predominant or normal succession of the beds, considerable differences occur when the rocks are traced across the country. Thus the Forest Marble attains a thickness of 450 feet in Dorsetshire, but dwindles down to only 15 feet at Blenheim Park. The Inferior Oolite consists of marine limestones and shales in Gloucestershire, but chiefly of massive estuarine sandstones and shales in Yorkshire. These differences help to bring before us some of the geographical features of the British area during the Jurassic period.

The LIAS consists of three formations, well marked by physical and palaeontological characters. In the lower member numerous thin blue and brown limestones with partings of dark shale are surmounted by similar shales with occasional nodular limestone bands, the whole being divided into seven zones, each characterized by the presence of one or more distinctive species of ammonite. From this point of the geological series up to the close of the Mesozoic formations, the ammonites play a chief part among the mollusks. The Middle Lias, consisting of argillaceous limestones (marlstones) with micaceous sands and clays, is divided into five ammonite zones. In its Yorkshire development this subdivision is remarkable for containing a bed of earthy carbonate of iron 15 to 20 feet thick, which has been extensively worked in the Cleveland district. The upper division is composed chiefly of clays and shales with nodules of limestones, among which three ammonite zones have been noted in Yorkshire.

The organic remains of the Lias comprise leaves and other remains of cycads (*Palaocycas*), conifers (*Foxites*, *Cupressus*, *Pinus*), ferns (*Oleopteris*, *Aldopteris*, &c.), and reeds (*Equisetites*). These fossils serve to indicate the general character of the flora, which seems now to have been mainly cycadeaceous and coniferous, and to have presented a great contrast to the lycopodiaceous vegetation of Paleozoic times. The occurrence of land-plants dispersely throughout the English Lias shows also that the strata, though chiefly marine, were deposited within such short distance from shore, as to receive from time to time leaves, seeds, fruits, twigs, and stems from the land. Further evidence in the same direction is supplied by the numerous insect remains, which have been obtained principally from the Lower Lias. These were, no doubt, blown off the land and fell into shallow water, where they were preserved in the silt on the bottom. The *Neuroptera* are numerous, and include several species of *Eubolita*. The coleopterous forms comprise a number of beetles. These were likewise representatives of the orthopterous, hemipterous, and dipterous orders. These relics of insect-life are so abundant in some of the calcareous bands that the latter are known as insect-beds. With them are associated remains of terrestrial plants, cycads, and mollusks, sometimes marine, sometimes apparently brackish-water. The marine life of the period has been abundantly preserved, so far at least as regards the comparatively shallow and litta-littoral waters in which the Liassic strata were accumulated. Corals, though on the whole scarce, abound on some horizons (*Isastrea*, *Montlivaltia*, *Syrtastrea*, &c.). The crinoids were represented by thick growths of *Helocrinus* and *Pentacrinus*. There were several kinds of starfishes, and also of sea-urchins (*Cylindrus*, *Diadema*, *Asterodonta*), all generically distinct from those of the Paleocene periods. The contrast between the Liassic crustacea and those of the older systems, as Phillips has pointed out, is very decided, the ancient trilobites having entirely disappeared, and having been succeeded by tribes of long-tailed ten-footed lobsters and prawns. There is a similar striking difference between the mollusks of the Lias and those of the Paleozoic rocks, bearing witness to the great biological

changes which had taken place in the long interval. The brachopods are chiefly species of *Rhynchonella* and *Terebratulina*—genera which, though occurring in Paleozoic rocks, play there a comparatively subordinate part. They include the last *Spurifer* and *Leptæna* Of the lamellibranchs, a few of the most characteristic genera are *Gryphæa*, *Lima*, *Pecten*, *Modiola*, *Cardium*, *Hippodorum*, *Myacites*, and *Pholadomya*. Gastropods, though usually rare in such muddy strata as the greater part of the Lias, occasionally occur, but most frequently in the calcareous zones. Altogether 89 species are at present known, the chief genera being *Pseudonaria*, *Turbo*, *Eucypris*, *Cardium*, and *Chemnitzia*. The cephalopods, however, are the most abundant and characteristic shells of the Lias, the family of the ammonites numbers in Yorkshire at least 113 species. As already stated, some species are so distinctive of special horizons that the whole of the Lias has been subdivided into zones, each denoted by the name of its characteristic ammonite. In ascending order, these zones are named as follows.—In the Lower Lias,—1st, *Ammonites planorbis*, 2d, *A. angulatus*, 3d, *A. Bucklandi*, 4th, *A. tuberculatus*, 5th, *A. obtusus*, 6th, *A. apiculatus*, 7th, *A. varicosus*. In the Middle Lias,—1st, *A. Jamesoni* and *amaratus*, 2d, *A. capricornus*, 3d, *A. nungarringtoni*, 4th, *A. spinatus*, 5th, *A. anaxinus*. In the Upper Lias,—1st, *A. serpentinus*, 2d, *A. coniformis*, 3d, *A. jurensis*. The genus *Nautilus* is also present. The dibranthate cephalopods are represented by upwards of 40 species of the genus *Scleromus*. Numerous species of fishes have been obtained from the Lias. Some of these are peculiar, known only by their teeth (*Aciodus*, *Cycloodus*), others only by their spines (*Neoncutulus*), and some by both teeth and spines (*Rhyodon*). The ganoids are frequently found entire, the genus *Dapedius*, *Pholidophorus*, *Echinodus*, *Lepidotus*, *Pachycormus*, and *Leptolepis* being among the most frequent. But undoubtedly the most important paleontological feature of the Lias is the number and extraordinary interest of its reptilian remains. These include the extinct order of anhalosaurs or sea-lizards, uniting characters which are not found together in any living forms. Among these are the genus *Ichthyosaurus*, a creature with a fish-like body, two pairs of strong swimming paddles, and probably a vertical tail-fin. The head, joined to the body without any distinct neck, was furnished with two large eyes, having a ring of bony plates round the eyeball, and with teeth that had no distinct sockets. Some of the skeletons of this creature exceed 24 feet in length. Contemporaneous with it was the *Plesiosaurus*, distinguished by its long neck, the large size of its paddles, the smaller size of its head, and the insertion of its teeth in special sockets, as in the higher saurians. These creatures seem to have haunted the shallow seas of the Liasic time. There were also huge winged bat-like reptiles (*Dimorphodon*), with huge heads, having teeth in distinct sockets, eyes like the *Ichthyosaurus*, and one finger of each foot prolonged to a great length, for the purpose of supporting a membrane for flight. The bones, like those of birds, were hollow and air-filled. Gigantic dinosaurs were likewise among the inhabitants of Britain during Liasic time. These were true reptiles, yet with peculiarities of structure, particularly in the hinder part of the skeleton, linking them with birds like the ostrich. To this order belongs the *Megalosaurus* from the Lias of Lyme Regis. Lastly, the true crocodiles had representatives in the Liasic waters and shores, in the genera *Teleosaurus* and *Stenosauros*.

THE LOWER or BATH OOLITES lie conformably upon the top of the Lias, with which they are connected by a general similarity of organic remains. Out of the 312 known species in the Upper Lias, about 39 or 40 pass up into the overlying formation. The lowest of the three subdivisions of the English Oolites consists in the south-west and centre of England of shelly marine limestones, with clays and sandstones, but, as these strata are traced northwards into Northampton, Rutland, and Lincolnshire, they pass into a series of strata indicative of deposit in the estuary of some river descending from the north, for, instead of the abundant cephalopods of the truly marine and typical series, we meet with fresh-water genera such as *Cyrena* and *Unio*, with marine forms such as *Ostrea* and *Modiola*, thin seams of lignite, and remains of terrestrial plants. These indications of the proximity of land become still more marked in Yorkshire, where the strata (800 feet thick) consist chiefly of sandstones, shales with seams of ironstone and coal, and occasional horizons containing marine shells. It is deserving of notice that the Cornbrash, which forms the top of the Lower Oolite in the typical Gloucestershire district, occurs likewise in the same position in Yorkshire. Though rarely more than 8 feet thick, it runs across the country from Devonshire to Yorkshire.

Thus a distinctly defined series of beds of an estuarine character, exactly representative of the marine formations of the south-west, shows us that at the close of the Lower Oolitic period the estuary of the northern tract was submerged, and a continuous sea-floor stretched across the whole of the south-east of England.

Thanks to the deposits of the Yorkshire estuarine series our knowledge of the Oolite is much more ample than of the Liasic flora. With the exception of a few littoral bivalves all the plants are of terrestrial forms. They comprise about 60 species of ferns, among which the genera *Propteris*, *Sphenopteris*, *Phleboteris*, and *Taeniopteris* are characteristic. Next in abundance come the cycads, of which more than 20 species are known, belonging to the genera *Ozoranites*, *Zarantes*, *Pinophyllum*, and *Cycadites*. Coniferous remains are not infrequent in the form of stems or fragments of wood, as well as in occasional twigs with attached leaves, the genera *Asavacites*, *Brachyphyllum*, *Thuyites*, *Picea*, *Palæzia*, *Cygnocarpus*, and *Taxites* have been recognized. The Inferior Oolite presents a tolerably copious suite of invertebrate remains, which resemble generally those of the Lias. The predominance of *Rhynchonella* and *Terebratula* over the rest of the brachopods becomes still more marked. *Gryphæa*, *Lima*, *Pecten*, *Cardium*, *Myacites*, *Amygdalus*, *Pholadomya*, *Trigona* are frequent shells, while ammonites and belemnites also occur, though much more sparingly than in the Lias below, and in some of the later subdivisions of the Oolitic series. The Fuller's Earth, though well-marked in the Bath district, where it is about 200 feet thick, does not in Oxfordshire, and contains only a few distinctive fossils, most of its forms being also found in the Inferior Oolite.

The Great or Bath Oolite consists, in Gloucestershire and Oxfordshire, of three groups of strata. At the base comes a series of thin-bedded limestones with sands, known as the Stonesfield Slate, in the centre lies a mass of shelly and yellow or cream-coloured often Oolitic limestones, with partings of marl or clay—the Great Oolite, while at the top lies a set of clays and shelly limestones, including the Bradford Clay, Forest Marble, and Cornbrash. The Stonesfield Slate, the lowest of these three zones, is a local but exceedingly important subdivision, which has furnished a large number of reptilian and some mammalian remains. It must have been deposited in shallow water close to thickly wooded shores.

About a dozen species of ferns have been found in the Stonesfield Slate, the genera *Pecopteris*, *Sphenopteris*, and *Taeniopteris* being still the prevalent forms. The cycads are chiefly species of *Palæozoia*, the conifers of *Thuyites*. With these drifted fragments of a terrestrial vegetation there occur remains of beetles, dragon-flies, and other insects which had been blown or washed off the land. The waters were tenanted by a few brachopods (*Rhynchonella* and *Terebratula*), by lamellibranchs (*Gemmula*, *Lima*, *Ostrea*, *Pecten*, *Astarte*, *Modiola*, *Trigona*, &c.), by gastropods (*Natica*, *Nerita*, *Patella*, *Trochus*, &c.), by a few ammonites and belemnites, and by placoid and ganoid fishes, of which about 50 species are known. The reptiles comprise representatives of turtles, with peculiar species of *Ichthyosaurus* and *Plesiosaurus*. The genus *Teleosaurus*, which occurs in the Yorkshire Lias, is among the organisms of the Stonesfield Slate. It was a true carnivorous crocodile, measuring about 18 feet in length, and is judged by Phillips to have been in the habit of venturing more freely to sea than the gharial of the Ganges and the crocodile of the Nile. The huge dinosaur *Megalosaurus* frequented the shores of the Stonesfield lagoons, walking probably on its massive hind legs, and feeding on the mollusks, fishes, and perhaps the small mammals of the district. It is estimated to have had a length of 25 feet, and to have weighed 2 or 3 tons. The flying reptiles were likewise represented by the *Pteranodon*, a harpy-like creature which was able to fly, to shuffle on land, or perch on rocks, perhaps even to dive in search of its prey. But the most important organic remains of the Stonesfield Slate are undoubtedly its mammals, of which three genera *Amphitherium*, *Phascodontherium*, and *Storognathus* have been determined. Only portions of lower jaws have yet been found, pointing doubtless to the fact that, as the animals were drifted from land, the lower jaws, unprotected by outer skin, were separated in decomposition from the rest of the body. These interesting relics were the first traces of mammalian life found in strata of such high antiquity. They are regarded as having belonged to small marsupial animals, to which living analogues exist in Australia. In the Great Oolite the remains of a gigantic saurian *Teleosaurus* have been found. According to Phillips it was probably, when standing, not less than 10 feet in height and 60 feet in length, a marsh-loving or river-side animal, living on the ferns, cycads, and conifers among which it dwelt.

In the MIDDLE or OXFORD OOLITES, the Oxford Clay, so called from the name of the county through which it passes in its course from the coast of Dorsetshire to that of Yorkshire, consists mainly of layers of stiff blue and brown clay. In its lower portion lies a marked zone of calcareous abundantly fossiliferous sandstone, known, from a place in Wiltshire, as the Kelaways Rock, which, after dying out in the midland counties, reappears on the Yorkshire coast. This zone contains about 150 species of fossils, of which nearly a half are found in lower parts of the Jurassic series, and about the same number pass upward into higher zones.

Among its characteristic forms is *Ammonites Callovensis*. The Oxford clay, from the nature of its material and the conditions of its deposit, is deficient in some forms of life which we do not doubt abundant in neighbouring areas of clearer water. Thus there are hardly any corals, few echinoderms, polyzoa, or naupliopods. Some lamellibranchs are abundant, particularly *Gryphæa* and *Ostrea* (both forming sometimes whole oyster-beds), *Lima*, *Arcula*, *Pecten*, *Astarte*, *Trigonia*—the whole having a great similarity to the assemblages in the Lower Oolite formations. The gastropods are not so numerous as in the calcareous beds below, but belong mostly to the same genera. The ammonites are numerous—*A. Zuercheri*, *A. Jason*, *A. Lambertii*, and *A. oculatus* being characteristic. Of the belemnites, which also are frequent, *B. hastatus* is found all the way from Dorsetshire to Yorkshire. Spines and teeth of placoid fishes and entire specimens of *Leptodus* are occasionally to be met with. The reptiles, besides *Ichthyosaurus*, *Megalosaurus*, *Plesiosaurus* (4 species), *Stenocranius*, and *Rhamphorhynchus*, comprise also *Plesiosaurus*—a marine saurian with large head, short neck, paddles similar to those of *Plesiosaurus*, approaching the type of the ichthyosaurs, but even surpassing them in size.

The Coralline Oolite can likewise be traced, with local modifications and partial interruptions, across England from Yorkshire to Dorsetshire. It is named from its beds full of masses of coral. It consists of three zones,—a lower calcareous grit, a central rubbly limestone with corals (the true "coral rag" of William Smith), and an upper calcareous grit, which, though feebly represented further south, attains importance in Yorkshire. It is frequently entirely made up of comminuted shells, urchins, corals, and other marine organisms. The corals include the genera *Isastræa*, *Thamnastræa*, and *Thecosmilia*. The urchins belong to *Cidaris*, *Hemicidaris*, *Pigurus*, *Pugaster*, and other genera. There are likewise *Ammonites*, *Belemnites*, and *Nautili*.

The UPPER or PORTLAND OOLITES bring before us the closing epochs of the long Jurassic period in England, with the records of some of the physical revolutions which led to this change. At their base lies the Kimmeridge Clay, so named from the locality on the coast of Dorsetshire where it is so well exhibited, and whence it is traceable continuously, save where covered by the Chalk, into Yorkshire. Like the Oxford Clay below, it is distinguished by its thickness, persistence, and peculiar organic remains.

Molluscs appear in greatly diminished variety. *Gryphæa virgula*, *Ostrea deltoidea*, *Astarte Hartwoodensis*, and *Cerium stratum* are characteristic species. The reptiles are the most important of the paleontological contents of this zone. They include remains of turtles, 5 species of *Ichthyosaurus*, 5 of *Plesiosaurus*, 8 of *Plesiosaurus*, *Celeosaurus*, *Megalosaurus*, and the crocodilians *Stenocranius*, *Telosaurus*, and *Gomphos*.

The Portland beds are so named from the Isle of Portland, where they directly succeed the Kimmeridge Clay. A feeble representative of them is believed to overlie that clay on the Yorkshire coast, but it is in the southern counties that they attain their chief development. They consist, at Portland, of a lower sandy set of beds about 150 feet thick, and of an upper calcareous zone (containing the well-known limestones so largely used for building purposes under the name of Portland stone) about 70 feet thick.

The fossils, which very commonly occur as mere empty casts, include as characteristic species *Isastræa oblonga*, *Cerium dissimile*, *Trigonia gibbosa*, and *Terebra Portlandica*. There occur also remains of some of the great Oolitic saurians.

The Purbeck beds, so named from the Isle of Purbeck, where they are best developed, are usually connected with

the foregoing formations as the highest zone of the Jurassic series of England. But they are certainly separated from the rest of that series by many peculiarities, which show that they were accumulated at a time when the physical geography and the animal and vegetable life of the region were undergoing a remarkable change.

They have been arranged in three groups. The lowest consists of fresh-water limestones and clays, with layers of ancient soil containing stamps of the trees which grew in them. The middle group comprises about 120 feet of strata with marine fossils, while the highest division shows a return of fresh-water conditions. Among the indications of the presence of the sea is an oyster bed (*Ostrea deltoidea*), 12 feet thick, with *Pecten*, *Machæla*, *Arcula*, *Thracia*, &c. The fresh-water bands contain still living genera of lacustrine and fluviatile shells—*Paludina*, *Lamæna*, *Planorbis*, *Physa*, *Valvata*, *Unio*, and *Cyclus*. Numerous fishes, both placoid and ganoid, haunted these Purbeck waters. Many insects, blown off from the adjacent land, sank and were entombed and preserved in the calcareous mud. These include coleopterous, orthopterous, hemipterous, nemopterous, and dipterous forms. Remains of several reptiles, chiefly chelonian, but including the Jurassic crocodile *Gomphos*, have also been discovered. But the most remarkable organic remains of the Purbeck beds are those of 10 genera and 25 species of marsupial mammals, from the size of a mole to that of a polecat. They are believed to have been mostly insectivorous. One of them (*Zuercherodon major*) is regarded by Owen as carnivorous, and probably about the size of the existing *Dasypus novæ angliæ* of Australia. These mammalian remains occur, almost wholly as lower jaws, in a stratum about 6 inches thick lying near the base of the Middle Purbeck group.

CONTINENTAL EUROPE.—Jurassic rocks cover a vast area in central Europe. They rise from under the Cretaceous formations in the north-east of France, whence they range southwards down the valleys of the Saône and Rhone to the Mediterranean. They appear as a broken border round the old crystalline nucleus of Auvergne. Eastwards they range through the Jura Mountains up to the high grounds of Bohemia. They appear in the outer chains of the Alps on both sides, and on the south they rise along the centre of the Apennines, and here and there over the Spanish peninsula. Covered by more recent formations they underlie the great plain of northern Germany, whence they range eastwards and occupy large tracts in central and eastern Russia. According to Neumayr, three distinct geographical regions of deposit can be made out among the Jurassic rocks of Europe. (1.) The Mediterranean province, embracing the Pyrenees, Alps, and Carpathians, with all the tracts lying to the south. One of the biological characters of this area was the great abundance of ammonites belonging to the groups of *Heterophylli* (*Phylloceras*) and *Pembriati* (*Lytoceras*). (2.) The central European province, comprising the tracts lying to the north of the Alpine ridge, and marked by the comparative rarity of the ammonites just mentioned, which are replaced by others of the groups *Infusati* (*Aspidoceras*) and *Oppellii*, and by abundant reefs and masses of coral. (3.) The boreal or Russian province, comprising the middle and north of Russia, Spitzbergen, and Greenland. The life in this area was much less varied than in the others, showing that in Jurassic times there was a perceptible diminution of temperature towards the north. The ammonites of the more southern tracts here disappear, together with the corals.

In France the following arrangement has been made of the Jurassic rocks, the subdivisions nearly corresponding to those first proposed in England:—

- (Purbeck beds not recognized.)
 Terrain Portlandien (Calcaire tacheté de Boulogne).
 „ Kimmeridgien (Argile de Hamflour).
 „ Corallien (Calcaire Corallien).
 „ Oolifère (Oolithe de Tréville).
 „ Callovien (Argiles du Diva = Kelaways Rock).
 „ Bathonien (Oolithe de Chen = Cornishen, Terre à foulon).
 „ Bajocien on Oolithe Inférieure (Oolithe du Bayeux).

 „ Liasien (Marnes et calcaires à Belemnites = Middle Lias).
 „ Sinuaurien (Calcaire à Gryphées = Lower Lias).

In north-western Germany the subjoined classification has been adopted.

Upper or White Jura (Malm)	Upper	Purbeck group (Seipulit, Munder Meigel, and Embeckhauser Plattenkalk)
		Kimeridge group (Upper, with <i>Ammonoites gigas</i> and <i>Erygyra virgula</i> , Lower or Neimeen-Schichten)
		Oxford group (Upper, with <i>Cidaris florentina</i> . Lower, with <i>Griffithia dilatata</i>)
Middle or Brown Jura (Dogger)	Upper	Clays with <i>Ammonoites oedus</i>
		Shales with <i>Ammon. macrocephalus</i>
		Cornbrash with <i>Ammonia cuneolata</i> , <i>Ammon. posterus</i>
Lower	Middle	Shales with <i>Orthis Knorr</i> , <i>Ammon. ferrugineus</i>
		Zone of <i>Ammon. Parkinsoni</i>
		Coronaten-Schichten, clays with <i>Belemnites giganteus</i> , <i>Ammon. Humphreysianus</i> , <i>Ammon. Brakenridg.</i>
Lower or Black Jura (Lias)	Upper	Shales with <i>Inoceramus polyplocus</i> , <i>Ammon. Murchisona</i>
		Clays and limestones with <i>Ammon. opalinus</i>
		Grey marls with <i>Ammonoites yuensis</i>
Middle	Middle	Bituminous shales (Posidonien-schiefer) with <i>Ammon. lythensis</i> , <i>A. communis</i> , <i>A. byrons</i> , <i>Posidonina Bronni</i>
		Clays with <i>Ammon. amaltha</i>
		Marls and limestones with <i>Ammon. capricornus</i>
Lower	Lower	Dark clays and ferruginous marls with <i>Ammon. brevispinna</i>
		Clays with <i>Ammon. planicosta</i>
		Blue grey clays with <i>Ammon. Bucklandi</i> (Arietenschichten)
Lower	Lower	Dark clays with <i>Ammon. angulatus</i>
		Dark clays and sandy layers with <i>Ammon. planorbis</i> (<i>psilonotus</i>)

NORTH AMERICA.—So far as yet known rocks of Jurassic age play but a very subordinate part in North American geology. Perhaps some of the red strata of the Trias belong to this division, for it is difficult, owing to paucity of fossil evidence, to draw a satisfactory line between the two systems. Strata containing fossils believed to represent those of the European Jurassic series have been met with in recent years during the explorations in the western domains of the United States. They occur among some of the eastern ranges of the Rocky Mountains, as well as on the western side of the watershed. They have been recognized also far to the north beyond the great region of Aztec and Palaeozoic rocks in the arctic portion of the continent. They consist of limestones and marls, which appear seldom to exceed a few hundred feet in thickness. The fossils include species of *Pentacrinus*, *Monotis*, *Trigonia*, *Lima*, *Ammonites*, and *Belemnites*.

CRETACEOUS.

The next great series of geological formations is termed the Cretaceous system, from the fact that in England and western Europe one of its most important members is a thick band of white chalk (*creta*).

BRITAIN.—The Purbeck beds bring before us evidence of a great change in the geography of England towards the close of the Jurassic period. They show how the floor of the sea in which the thick and varied formations of that period were deposited came to be gradually elevated, and how into pools of fresh and brackish water the leaves, insects, and small marsupials of the adjacent land were washed down.

These evidences of terrestrial conditions are followed in the same region by a vast delta-formation, that of the Weald, which accumulated over the south of England, while the older parts of the Cretaceous system were being deposited in the north. Hence there are two types of that system, one where the strata are fluviatile or estuarine, termed the Wealden type, the other where they are marine, known as the Neocomian type. Arranged in descending order the following are the subdivisions of the English Cretaceous rocks:—

Upper Cretaceous	Chalk	Upper Chalk with flints	600 to 1200 ft
		Lower Chalk without flints	
		Chalk Marl (Grey Chalk)	
Upper Greensand	Upper Greensand	Greenish-grey sandstones and sands	40 ,, 150 ,,
		Stiff blue clay with calcareous and pyritous nodules	100 ,, 150 ,,
		Gault	
Lower Cretaceous or Neocomian	Fluviatile Type	Marine Type	
		Folkstone beds	70 to 100 ft.
		Sandgate beds	75 ,, 100 ,,
Lower Cretaceous or Neocomian	Weald Clay, 1000 ft	Hythe beds	75 ,, 100 ,,
		Atherfield clay	30 ,, 60 ,,
		Upper part of Speeton Clay	150 ,,
Lower Cretaceous or Neocomian	Hastings beds consisting of—Tunbridge Wells Sand (140–380 ft)	Punfield beds, Tealby beds, and middle part of Speeton Clay	150 ,,
		Lower part of Speeton Clay	200 ,,
Lower Cretaceous or Neocomian	Wadlun Clay (120–180 ft)	Wadlun Clay (120–180 ft)	
		Wadlun Sand (400 to 600 ft)	

Lower Cretaceous or Neocomian.—The fluviatile development of this series in the south of England consists of a great depth of sands and clays known generally as the Wealden series, from the Weald of Sussex and Kent, where they are best displayed.

They precisely resemble the deposits of a delta, and this is borne out by their organic remains, which consist partly of terrestrial plants (*Equisetum*, *Sphenopteris*, *Alathopteris*, *Thuyites*, *Cyrtos*, and *Conifers*), and fresh-water shells (*Unio*, 10 species, *Cyrena*, 5 species, with *Cyclas*, *Palaemon*, *Melania*, &c.), with a few estuarine or marine forms as *Ostrea* and *Mytilus*, and ganoid fishes (*Lepidotus*) like the gar of American rivers. Among the spoils of the land floated down by this river were the carcasses of huge dinosaurian reptiles (*Iguanodon*, *Hylaeosaurus*, *Megalosaurus*), of the long necked plesiosaurs, and of winged pterodactyls. The detrital formation in which these remains occur extends in an east and west direction for at least 200 miles, and from north to south for at least 100. Hence the delta must have been not less than 20,000 square miles in area. It has been compared with that of the Quorn; in reality, however, its extent must have been greater than its present visible area, for it has suffered from denudation, and is to a large extent concealed under more recent formations. The river probably descended from the north-west, draining a vast area, of which the existing mountain groups of Britain are perhaps merely fragments.

The marine type of the Lower Cretaceous rocks is now commonly termed Neocomian, from Neufchâtel (*Neocomium*), where it is well developed. In the south of England only the upper division appears, overlying conformably the Wealden series, and showing the gradual depression of the old delta and the advance of the sea. In Yorkshire, however, a thick deposit known as the Speeton Clay has been ascertained by Mr Judd to pass down into the Jurassic system, and to contain a representation of the upper parts of the Neocomian of the Continent.

The lower division of the Speeton Clay contains, among other fossils, *Ammonites Noricus*. The central zone is marked by *Pecten cinctus*, *Anguloceras Duvallii*, and *Meyera ornata*. The upper division is characterized by *Pecten Malleti*, *Ammonites Deshayesi*, *Pecten orbicularis*. It is the fossils of this upper division which occur in the Lower Greensand of Kent. They amount to about 300 species, of which only 18 or 20 per cent. pass up into the Upper Cretaceous. This marked palaeontological break, taken in connexion with traces of unconformity between the Lower Greensand and the Gault, shows that a definite geological boundary-line can be drawn between the lower and upper parts of the Cretaceous system.

Upper Cretaceous.—At the base of this series lies the Gault—a dark blue stiff clay or marl, sometimes sandy and calcareous. It overlaps the older parts of the Cretaceous series, and in Wiltshire lies on Kimeridge Clay. Among the characteristics fossils of this division are *Cyclocyathus Fittoni*, *Caryophyllia Bowerbanki*, *Nucula pectinata*, *Inoceramus sulcatus*, *Natica Gaultina*, *Rostellaria carinata*, *Ammonites dentatus*, and *Hamites attenuatus*. In all, about 200 species of fossils occur, of which about 46 per cent. pass into the Upper Greensand.

The Gault is overlaid by a group of sands and sandstones often of a greenish tint from the presence of glauconite grains. Hence the name Upper Greensand which is applied to them. These strata can be traced westwards into Devonshire, and eastwards to the headlands of Kent, but they die out towards the north. Then mineralogical characters and variable thickness seem to point to them as deposits of the shore of the sea in which the chalk was subsequently laid down upon them.

Among their characteristic fossils are the sponges *Siphonia pyramis* and *S. costata*, members of the genera *Cidaris*, *Echinus* and *Salenia*, numerous *Terebratula* and *Rhynchonella*, many lamellibranchs, particularly of the genera *Ecogyra*, *Ostrea*, *Gryphæa*, *Lima*, *Pecten*, and *Trigonia*, and gastropods of the genera *Natica*, *Turritella*, and others. The cephalopods abound and comprise many forms of *Ammonites* (40 species), *Hamites*, *Scaphites*, *Baculites*, *Nautilus*, and *Belemnites*.

Chalk.—This conspicuous member of the Cretaceous system has at its base a white or pale yellow marl with green grains of glauconite, phosphatic nodules, and iron pyrites (Chloritic Marl), which is succeeded sometimes by a kind of argillaceous chalk (Chalk Marl) forming the base of the true Chalk. It can be traced from Flamborough Head in Yorkshire across the south-eastern counties to the coast of Dorset. Throughout this long course its western edge usually rises somewhat abruptly from the plains as a long winding escarpment, which from a distance often reminds one of an old coast line. The upper half of the Chalk is generally distinguished by the presence of many nodular layers of flint. With the exception of these enclosures, however, the whole formation is a remarkably pure white pulverulent dull limestone, meagre to the touch, and soiling the fingers. It is composed mainly of crumbled foraminifera, with the mingled debris of urchins, corals, and mollusks. It must have been accumulated in a sea of some depth and tolerably free from sediment, like some of the foraminiferal ooze of the existing sea-bed. There is, however, no evidence that the depth of the water at all approached that of the abysses in which the present Atlantic globigerina-ooze is being laid down. Indeed, the character of the foraminifera, and the variety and association of the other organic remains, are not like those which have been found to obtain now on the deep floor of the Atlantic.

Somewhere about 800 species of fossils are known from the English Chalk. Occasional rare fragments of terrestrial wood occur, perforated by the teredo, and telling of a transport of some distance from land. Sponges are numerous. They have usually been silicified and preserved in the flint nodules. Among the more characteristic genera are *Ocinacites*, *Cliona*, *Vesiculites*, *Brachioites*, *Spongia*, and *Siphonia*. Careful preparation of a fragment of chalk usually brings to light remains, sometimes well preserved, of foraminifera, *Rotalia ovata*, *Cristatella rotulata*, *Globigerina bulloides*. Corals are represented by about 15 species (*Præactinia*, *Calceolaria*, *Caryophyllia*, &c.). The *echina* form one of the most conspicuous features among the Chalk fossils, from their individual numbers and their variety of forms. Among the more common genera the following may be named—*Annelites*, *Echinoceros* (*Galerites*), *Cardaster*, *Melastor*, *Cyphosoma*, *Cidarites*, *Pseudocidarites*, *Dicoidites*, and *Salenia*. Among other star-fishes the genus *Goniatites* occurs in numerous species in the upper division of the Chalk. The crinoids were represented in the sea of the period by a *Crematula*, one or two *Pentacrinoids*, *Megacrinus*, and *Euryacrinus*. Polyzoa abound in the Upper Chalk (*Homoniscus*, *Pustulopora*, *Holostoma*, &c.). The brachiopods appear in the form of great numbers of *Rhynchonella*, *Terebratula*, and *Terebratulina*, with *Crania*, *Thecidia*, and *Kinopsis*. Among the lamellibranchs the genera *Ostrea*, *Pecten*, *Inoceramus*, and *Lima* are particularly frequent. Gastropods are comparatively few, *Pleurodonaria perspectiva* being one of the few forms found both in the lower and upper division of the Chalk. Cephalopods, however, abound; characteristic species are *Belemnites pleius*, *B. mucronata*, *Nautilus Delongchampsianus*, *Ammonites nauticularis*, *A. varians*, *A. Bathoniensis*, *Turritites costatus*, *Baculites baculoides*, *Scaphites aqualis*, and *Hamites armatus*. Upwards of 80 species of fish have been discovered. These include chimeroids (*Eldonodon*, *Ichthyodus*), sharks (*Egylodus*, *Phylodus*, *Lamna*, *Otodus*), ganoids (*Megacrinus*, *Pycnodon*), and teleostean or bony fishes (*Beryx*, *Euchodus*, *Sauracanthus*). Numerous reptilian remains have been found, more par-

ticularly in a bed about 1 foot thick lying at the base of the Chalk of Cambridge, and largely worked for phosphate of lime derived from reptilian coprolites and bones. Among the known forms are several chelonians, the great desmosaur *Acanthopholis*, several species of *Platanodon*, 5 or 6 species of *Ichthyosaurus*, 10 species of *Pterodactylus* from the size of a pigeon upwards, one of them having a spread of wing amounting perhaps to 25 feet, 8 species of *Mosasaurus*, a crocodilian (*Polychaetodon*), and some others. At Cambridge also the bones of one or two species of birds have been found, probably belonging to *Naturales* allied to the living gulls.

CONTINENTAL EUROPE.—The Cretaceous system in many detached areas covers a large extent of the Continent. From the south of England it spreads southward across the north of France up to the base of the ancient central plateau of that country. Eastwards it ranges beneath the Tertiary and post-Tertiary deposits of the great plain, appearing on the north side at the southern end of Scandinavia and in Denmark, on the south side in Belgium and Hanover, round the flanks of the Harz, in Bohemia and Poland, eastwards into Russia, where it covers many thousand square miles up to the southern end of the Ural chain. To the south of the central axis in France, it underlies the great basin of the Garonne, flanks the chain of the Pyrenees on both sides, spreads out largely over the eastern side of the Spanish table-land, and reappears on the west side of the crystalline axis of that region along the coast of Portugal. It is seen at intervals along the north and south fronts of the Alps, extending down the valley of the Rhone to the Mediterranean, ranging along the chain of the Apennines into Sicily and the north of Africa, and widening out from the eastern shores of the Adriatic through Greece, and along the northern base of the Balkans to the Black Sea, round the southern shores of which it ranges in its progress into Asia, where it again covers an enormous area.

A series of rocks covering so vast an extent of surface must needs present many differences of type, alike in their lithological characters and in their organic contents. They have before us the result of a time when one continuous sea stretched over all the centre with most of the south of Europe, covered the north of Africa, and swept eastwards to the far east of Asia. There were doubtless many islands and ridges in this wide expanse of water, whereby its areas of deposit and biological provinces must have been more or less sharply defined. Some of these barriers can still be traced, as will be immediately pointed out.

The accompanying table contains the subdivisions of the Cretaceous system which have been adopted in a few of the more important areas of Continental Europe.

It will be seen from this table that while there is sufficient palæontological similarity to allow a general parallelism to be drawn among the Cretaceous rocks of western Europe, there are yet strongly marked differences pointing to very distinct conditions of life, and probably, in many cases, to disconnected areas of deposit. Nowhere can these contrasts be more strikingly seen than in crossing from the Cretaceous basin of the Loire to that of the Garonne. In the north of France, the Upper Cretaceous beds are scarcely like those of England, the soft white Chalk forming a conspicuous feature in both countries, but, on the south side of the great axis of crystalline rocks, the soft chalk is replaced by hard limestones. There is a prevalence of calcareous matter, often sparry, throughout the whole series of formations, with comparatively few sandy or clayey beds. This mass of limestone attains its greatest development in the southern part of the department of the Dordogne, where it is said to be about 800 feet thick. But the lithological differences are not greater than those of the fossils. In the north of France, Belgium, and England, the singular molluscan family of the *Hippuritidae* or *Buculites* appears only occasionally and sporadically in the Cretaceous rocks, as if a stray individual had from time to time found its way into the region, but without being able to establish a colony there. In the south of France, however, the hippurites occur in prodigious quantity. They often mainly compose the limestones, hence called hippurite limestones (Rauten-Kalk). They attained a great size, and seem to have grown on immense banks like our modern oyster. They appear in successive species on the different stages of the Cretaceous system, and can be used for marking palæontological horizons, as the cephalopods are elsewhere. But while these lamellibranchs played so important a part throughout the Cretaceous period in the south of France, the numerous ammonites and belemnites, so characteristic of the Chalk in England, were absent from that region. This very distinctive type of hippurite limestones has so

much wider an extension than the English type of the Cretaceous system that it should be regarded as really the normal development. It ranges through the Alps into Dalmatia, and round the great Mediterranean basin far into Asia. Gumbel has proposed to group the European Cretaceous rocks into three great regions—(1) the northern province, or area of white chalk with *Belonitella*,

Table showing the Subdivisions of the Cretaceous System in the West of Europe

	England	Northern France	North-West Germany and Denmark	Southern France.
Santonian		Danien, calcareous sandstone (p. 460)	Feroc chalk Maastricht chalk (p. 360)	
	Upper Chalk with flints	Craie blanche (Belonitella mucronata)	Oberquader sandstein (Belonitella mucronata, &c.)	Calcaires à nodules (Radolites)
Turonian	Lower Chalk without flints	Craie (Mastoceras coranum)	Oberquader sandstein (Mastoceras coranum)	
	Chalk Marl	Craie marneuse	Mittelquader Mittelpläne (Inoceramus, Ceras, and L. laticosta)	Calcaires à Hippurites (no Inoceramus, etc.) Radolites cornuosa
Cenomanian	Chloritic Marl	Craie grasse-marneuse		Calcaires marneux (Inoceramus latissimus)
	Upper Greensand	Gris vert supérieur	Unterquader, Unterpläne (Ammonites, Rotomagensis, A. variata)	Calcaires à Caprotina triangularis, et Ammonites Rotomagensis
Gault		Albion, argile marneuse ou sablonneuse.	Flammegauzei (Aucella gyphodonta) Clay (Belonitella nitens)	Albion, sables et gris verts ou ferrugineux et Thier-later
		Apert, argile à plicatures	Maile, &c. Ammonites tardifera, Belonitella, &c. Clays (Belonitella nitens)	Apert (Orbitulites lenticularis)
Lower Greensand		Urgonien	Argileux à bédouilles	Calcaires à caprotines
		Argiles et sables (Zonitella, Ostrea, &c.)	Hils clay (Hilston) No zinc, &c.	Néocomien supérieur (Zoceras complanatus), Calcaires à Spatangus
Neocomian or Eocene				
	Punfield and Towby beds and middle part of Speeton Clay	Calcaires marneux bleus (Zoceras complanatus)	Hils conglomerate clay (Mastoceras, Rhynchonella depressa)	Néocomien moyen, calcaire à Aptychus
World Clay and Hastings Sand				
	Lower part of Speeton Clay	Sables blancs et ferrugineux.	Düster-sandstein with coal seams	Néocomien inférieur (Zoceras Camptochelone)

comprising England, north France, Belgium, Denmark, Westphalia; (2) the Hercynian province, or area of *Scapha a cuneata*, embracing Bohemia, Moravia, Saxony, Silesia, and central Bavaria; and (3) the southern province, or area of hippurites, including the regions south of the crystalline axis of France, the Alps, and southern Europe.

The Wealden beds, with the Hastings Sands and Weald Clay, are found in north-west Germany. They contain abundant remains of terrestrial vegetation, which is sometimes aggregated into thin seams of black glancing coal, occasionally even as much as 64 feet thick. The main or typical Neocomian series attains a great development among the eastern Alps, where it consists mainly of massive white and grey limestones, divided into zones according to their characteristic fossils. Some geologists place in it a part of the massive Vienna sandstone (Wiener Sandstein) which enters so largely into the structure of the other Alps. The massive arenaceous formation formerly massed together under the general name of Quader-sandstein, but now found to be the equivalent of the calcareous bands of other regions, and capable of subdivision into the chief normal groups, forms a conspicuous feature in Saxony and Bohemia, as in the great gorge of the Elbe and the picturesque crags and pinnacles of Saxon Switzerland. From the Upper Cretaceous beds, in the neighbourhood of Aix-la-Chapelle, consisting of white sands and laminated clays 400 feet thick, a large number of terrestrial plants have been obtained. The number of species is estimated at more than 400. Of these 70 or 80 are cryptogams, chiefly ferns (*Gleichenia*, *Lygodium*, *Asplenium*, &c.), there are

numerous conifers (some akin to *Sequoia*), and three or four kinds of screw-pines (*Podocarpus*). This flora has a much more modern aspect than any other yet found in Secondary formations. But its most important feature is the occurrence of numerous true eugenean plants—the earliest yet found in Europe. The prevalent forms are *Protoceras*, many of them being referred to genera still living in Australia or at the Cape of Good Hope. There occur also species of oak, bog-myrtle, &c. These interesting fragments serve to indicate the modern character of the flora of Europe towards the close of the Cretaceous period, and to show that the climate, doubtless greatly warmer than that which now prevails, nourished a vegetation like that of some parts of Australia or the Cape. Further information has been afforded regarding the extension of this flora by the discovery in North Greenland of a remarkable series of fossil plants. From certain Lower Cretaceous beds of that Arctic region, Heer has described 30 species of ferns, 9 cycads, and 17 conifers; while, from the Upper Cretaceous rocks of Noursak, he enumerates species of poplar, fig, sassafras, ceder, and magnolia.

NORTH AMERICA.—The recent surveys of the western territories of the United States have greatly increased our knowledge of the Cretaceous system on the American continent, where it is now known to cover a vast expanse of surface, and to reach a thickness of sometimes 10,000 feet. Spawning developed in the eastern States, from New Jersey into South Carolina, it spreads out over a wide area in the south, stretching round the end of the long Paleozoic ridge from Georgia through Alabama and Tennessee to the Ohio; and reappearing from under the Tertiary formations on the west side of the Mississippi over a large space in Texas and the south-west. Its maximum development is reached in the western States and Territories of the Rocky Mountain region—Wyoming, Utah, and Colorado. Cretaceous rocks have likewise been detected in Arctic America near the mouth of the Mackenzie River.

Much controversy has been carried on among American geologists regarding the upper limit of the Cretaceous system, some maintaining, from the character of the plants and of the shells, that the great plant-bearing series termed the Lignitic is of Tertiary age, others insisting, from the occurrence of true Cretaceous shells in and above the Lignitic series, that it must belong to the Cretaceous system. In the Upper Missouri region Hayden and Meek established the following subdivisions:—

5. Fox Hills group.—Sandstones and sandy clays (*Belonitella*, *Nautilus*, *Ammonites*, *Baculites*, *Mossanus*, &c.) 500 ft.
4. Fort Pierre group.—Plastic clays (*Ammonites*, *Scaphites*, *Inoceramus*, &c.) 700 ,,
3. Niobrara group.—Calcareous marl (*Ostrea congesta*, *Inoceramus problematicus*, fish remains, &c.) 200 ,,
2. Fort Benton group.—Clays and limestones (*Scaphites*, *Ammonites*, *Pholidomya*, &c.) 800 ,,
1. Dakota group.—Sandstone, clays, and seams of lignite, with vast numbers of dicotyledonous leaves, a few marine shells. This is the great repository of the Cretaceous flora 400 ,,

American Cretaceous fossils include the earliest dicotyledonous plants yet found on this continent, upwards of 100 species having been found, of which one-half were allied to living American forms. Among them are species of oak, willow, poplar, beech, maple, hickory, fig, tulip-tree, sassafras, sequoia, American palm (*Sabal*), and cycads. The more characteristic mollusca are species of *Trochodonta*, *Ostrea*, *Gryphaea*, *Inoceramus*, *Hippurites*, *Radolites*, *Ammonites*, *Scaphites*, *Huastec*, *Baculites*, *Belonitella*, *Ancyloteres*, and *Thurridites*. Of the fishes of the Cretaceous seas 97 species are known, comprising large predeceus representatives of modern or osseous types like the salmon and sarpy, though cestracians and ganoids still flourished. But the most remarkable feature in the American Cretaceous fauna, as at present known, is the great number, variety, and size of the reptiles. According to the enumeration of Coe, who includes, however, in his list the Lignitic group here placed among the Tertiary formations, there are known at present 18 species of dinosaurs, 4 pterosaurs, 14 crocodilians, 13 sauropterygians or sea-saurians, 48 testudinates (turtles, &c.), and 60 pythonomorphs or sea-serpents. One of the most extraordinary of these reptilian forms was the *Elasmocormus*—a huge snake-like form 40 feet long, with slim arrow-shaped head on a swan-like neck using 20 feet out of the water. This formidable sea-monster “probably often swam many feet below the surface, raising the head to the distant air for a breath, then withdrawing it and exploring the

depths 40 feet below without altering the position of its body. It must have wandered far from land, and that many kinds of fishes formed its food is shown by the teeth and scales found in the position of its stomach" (Cope). But the real rulers of the American Cretaceous waters were the pythonomorphous saurians or sea-serpents. Some of them attained a length of 75 feet or more. They possessed a remarkable elongation of form, particularly in the tail, their heads were large, flat, and conus, with eyes directed partly upwards. They swam by means of two pairs of paddles, like the flippers of the whale, and the eel-like strokes of their flattened tail. Like snakes they had four rows of formidable teeth on the roof of the mouth, which served as weapons for seizing their prey. But the most remarkable feature in these creatures was the unique arrangement for permitting them to swallow their prey entire, in the manner of snakes. Each half of the lower jaw was articulated at a point nearly midway between the ear and the chin, so as greatly to widen the space between the jaws, and the throat must, consequently, have been loose and baggy like a peican's. Nine species of birds have been obtained from the American Cretaceous rocks. Three of these belonged to the order of *Natatores* or swimmers, which includes our modern gulls, ducks, and geese; four were *Gallinæ* or waders, while two belonged to a long extinct order, and united certain ichthyine and reptilian characters with those of birds. (See Cope, *Report of U.S. Geol. Surv. of Territories*, vol. 11, 1875; Marsh, *American Journ. Science*, 3d ser. 1. to 14; Ledy, *Smithsonian Contributions*, 1865, No. 192; Lesquereux, *Cretaceous Flora*, *Report of U.S. Geol. Surv. of Territories*, vol. 7.)

IV. TERTIARY OR CAINOZOIC

The close of the Secondary periods was marked in the west of Europe by great geographical changes, during which the floor of the Cretaceous sea was raised partly into land and partly into shallow marine and estuarine waters. These events must have occupied a vast period of time, so that, when sedimentation once more began in the region, the organic remains of the Secondary ages had (save in a few low forms of life) entirely disappeared and given place to others of a distinctly more modern type. In England, the interval between the Cretaceous and the next geological period represented there by sedimentary formations is marked by the abrupt line which separates the top of the Chalk from all later accumulations, and by the evidence that the Chalk seems to have been in some places extensively denuded before even the oldest of what are called the Tertiary beds were deposited upon its surface. There is evidently here a considerable gap in the geological record. We have no data for ascertaining what was the general march of events in the south of England between the eras chronicled respectively by the Upper Chalk and the overlying Thanet beds.

Here and there on the Continent a few scraps of evidences are obtainable which help to fill up this gap. Thus, on the banks of the Meuse at Maestricht, a series of shelly and polyzoan limestones with a conglomeratic base (*Système Maestrichtien* of Damont, who places it above his Senonian system in the Upper Cretaceous series) contains a mingling of true Cretaceous organisms with others which are characteristic of the older Tertiary formations. It contains, for example, the characteristic Upper Chalk crinoid, *Bourgetocrinus ellipticus*, in great numbers; also *Ostrea vesicularis*, *Baculites Fajazii*, *Belemnella mucronata*, and the great reptile *Mosasaurus*; but with these occur such Tertiary genera as *Voluta*, *Fasciolaria*, and others. At Faxoe, on the Danish island of Seeland, the uppermost member of the Senonian series contains in like manner a blending of well-known Upper Chalk organisms with the Tertiary genera *Cyprea*, *Oliva*, and *Mitra*. In the neighbourhood of Paris also, and in scattered patches over the north of France, a formation known as the pisolithic limestone occurs, which was formerly classed with the Tertiary formations, seeing that its fossils had more affinities with later than with older rocks. But the discovery in it of numerous distinctively Upper Cretaceous forms has led to its being placed at the top of the Senonian series, from which, however, it is marked off by a decided unconformability, for it rests on a

denuded surface of the White Chalk. These fragmentary formations are interesting, in so far as they help to show that, though in western Europe there is a tolerably abrupt separation between Cretaceous and Tertiary deposits, there was nevertheless no real break between the two periods. The one merged insensibly into the other; but the chronicles of the intervening ages have been in great measure destroyed.

In entering upon the Tertiary series of formations, we find ourselves upon the threshold of the modern type of life. The ages of lycopods, ferns, cycads, and yew-like conifers have passed away, and that of the dicotyledonous angiosperms—the hard-wood trees and evergreens of to-day—now succeeds them, but not by any sudden extinction and recreation, for, as we have seen (*ante*, p. 359), some of these trees had already begun to make their appearance even in Cretaceous times. The ammonites, baculites, and other cephalopods, which had played so large a part in the mollescan life of the Secondary periods, now cease. The great reptiles, too, which in such wonderful variety of type were the dominant animals of the earth's surface, alike on land and sea, ever since the commencement of the Liass, now wane before the increase of the mammalia, which advance in ever-augmenting diversity of type until man appears at their head.

The name Tertiary, given in the early days of geology before much was known regarding fossils and their history, has retained its hold on the literature of the science. It is sometimes replaced by the term Cainozoic (*recent life*), which expresses the great fact that it is in the series of strata comprised under this designation that most recent species and genera have their earliest representatives. Taking as the basis of classification the percentage of living species of mollusca found in the different groups of the Tertiary series, Lyell proposed a scheme of arrangement which has been generally adopted. The older Tertiary formations, in which the number of still living species of shells is very small, while, in fact, we seem to see as it were the first beginnings of the modern life, he named *Eocene* (*dawn of the recent*), including under that title those parts of the Tertiary series of the London and Paris basins wherein the proportion of existing species of shells was only 3½ per cent. The middle Tertiary beds in the valleys of the Loire, Garonne, and Dordogne, containing 17 per cent. of living species, were termed *Miocene* (*less recent*). The younger Tertiary formations of Italy were included under the designation *Pliocene* (*more recent*), because they contained a majority or from 35 to 95 per cent. of living species. This newest series, however, was further subdivided into Older Pliocene (35 to 50 per cent. of living species) and Newer Pliocene (90 to 95 per cent.). This classification, with various modifications and amplifications, has been adopted for the Tertiary group not of Europe only but of the whole globe.

As the North American development of the Tertiary series differs in so many respects from that of Europe, it will be most conveniently considered by itself after the European classification has been described.

Eocene.

GREAT BRITAIN.—The Eocene rocks of Britain are entirely confined to the south-east of the island, where they occupy two great depressions of the chalk, known respectively as the London and Hampshire basins. They have been arranged into the groups shown in the subjoined table.

Upper	Tertiary fresh-water and estuarine series	Hempstead beds.....		170 ft.
		Bembridge		115 "
		Osborne		70 "
		Headon		200 "

Middle	Middle main- series	Upper Bagshot Sand.	250 to 300 ft
		Middle Bagshot beds, includ- ing Baton Clay (300 feet) and Blacklesham beds (100 feet)	
		Lower Bagshot beds	100 ,, 150 ,,
Lower	Lower fresh- water, estu- arine, and marine	Oldhaven Clay	50 ,, 500 ,,
		Oldhaven beds	20 ,, 30 ,,
		Woolwich and Reading beds . .	15 ,, 165 ,,
		Thanet Sand	20 ,, 60 ,,

Grouped in relation to the physical changes which they record, these strata naturally stand in three divisions. At the base lies a series of beds laid down in fresh, estuarine, and sea-water, on an upraised denuded surface of Chalk. Then comes a central group bearing witness to the deepening of these shallow waters, and to the advance of the sea far up the former estuary. The upper group brings before us proof of the eventual retreat of the sea, and the conversion of the area once more into fresh-water lakes and rivers. This arrangement does not quite tally with that which is based on a comparison of the fossils with existing forms, and with those of other Tertiary districts, for it places the London Clay in the middle series, though the fossil evidence distinctly shows that formation to belong to the older Eocene groups.

Lower Eocene.—The Thanet Sand at the base of the London Tertiary basin consists of pale yellow and greenish sand, sometimes clayey, and containing at its bottom a layer of green-coated flints resting directly on the Chalk. According to Mr Whitaker, it is doubtful if any proof of actual erosion of the chalk can anywhere be seen under the Tertiary deposits in England, and he states that the Thanet Sands everywhere lie upon an even surface of chalk with no visible unconformability. Professor Phillips, on the other hand, describes the chalk at Reading as having been "literally ground down to a plan or undulated surface, as it is this day on some parts of the Yorkshire coast," and having likewise been abundantly bored by lithodomous shells. The fossils of the Thanet Sand comprise about 70 known species (all marine, except a few fragments of terrestrial vegetation). Among them are several foraminifera, numerous lamelli-branchia (*Astarte tenera*, *Cyprina Morrisii*, *Ostrea Bellovacina*, &c.), a few species of gastropods (*Natica subdepressa*, *Aporrhais Sowerbi*, &c.), a nautilus, and the teeth or palatal bones of fishes (*Lamna*, *Pseudus*).

The Woolwich and Reading beds, or Plastic Clay of the older geologists, consist of lenticular sheets of plastic clay, loam, sand, and pebble beds. The organic remains show that the sea of the Thanet Sand era gradually shallowed into an estuary. They amount to more than 100 species, and include a few plants of terrestrial growth such as *Fucus Forbesi*, *Grevillea Heeri*, and *Laurus Hookeri*. The lamelli-branchia are partly estuarine or fresh-water (*Cyclus*, *Cyrena*, *Dreissena*, *Unio*), partly marine. Of the latter a characteristic species is *Ostrea Bellovacina*, which forms a thick oyster bed at the base of the series. *Ostrea tenera* is likewise abundant. The gastropods include a similar mixture of marine with fluviatile species (*Cerithium fundatum*, *Melania inquinata*, *Natica subdepressa*, *Fusus latus*, *Paludina lenta*, &c.). The fish are chiefly sharks (*Lamna*). Bones of turtles and scutes of crocodiles have been found. The highest organisms are bones of mammalia, one of which, the *Coryphodon*, was allied to the modern tapir.

The Oldhaven beds forming the base of the London Clay, though of trifling thickness, have yielded upwards of 150 species of fossils. Traces of *Fucus*, *Cinnamomum*, and *Conifera* have been obtained from them; but the organisms are chiefly marine and partly estuarine shells, the gastropods being particularly abundant. The London Clay, as its name implies, is a mass of clay, stiff, brown, or bluish-grey, with septarian nodules. It extends through both the

London and Hampshire basins, attaining a maximum thickness in the south of Essex. It has yielded a long and varied suite of organic remains, from which we can see that it must have been laid down in the sea beyond the mouth of a large estuary, into which abundant relics of the vegetation, and even sometimes of the fauna of the adjacent land were swept. Its fossils are mainly marine molluscs, and, taken in connexion with the flora, indicate that the climate was somewhat tropical in character. The plants include the fruits or other remains of palms (*Nypadites*), custard-apple, acacia, gourds, melons, *Proteacea*, and *Conifera*. Crustacea abound (*Xanthopoda*, *Hoplopoda*). Gastropods are the prevalent mollusks, the common genera being *Pleurotoma* (45 species), *Fusus* (15 species), *Cypræa*, *Murex*, *Cassidaria*, *Pyrula*, and *Voluta*. The cephalopods are represented by 6 or more species of *Nautilus*, by *Beloserpis sepioides*, and *Beloptera Lesnœui*. Nearly 100 species of fishes occur in this formation, the rays (*Mylobates*, 14 species) and sharks (*Lamna*, *Otodus*, &c.) being specially numerous. A sword-fish (*Xiphiopsis grœcus*), and a saw-fish (*Pristis baulcatus*) about 10 feet long, have been described by Agassiz from the London Clay of Sheppey, whence almost the whole of the fish remains have been obtained. The reptiles were numerous, but markedly unlike, as a whole, to those of Secondary times. Among them are numerous turtles and tortoises, two species of crocodile, and a sea-snake (*Palæophis*), estimated to have been 13 feet long. Remains of birds have also been met with; one of these (*Lathornis vulturnus*) appears to have been allied to the vulture, another (*Falcornis tobacicus*) to our modern king-fisher, besides waders and other types. The mammals numbered among their species a hog (*Hyacotherium*), several tapirs (*Coryphodon*, &c.), an opossum (*Didelphys*), and a bat. The carcasses of these animals must have been borne seawards by the great river which transported so much of the vegetation of the neighbouring land.

Middle.—The Bagshot group consists of sand and bands of clay which, in the Hampshire basin, are tolerably fossiliferous. As developed in the Isle of Wight and at Bourne-mouth, their lower members have yielded a large number of terrestrial plants, among which the *Proteacea* are still numerous, together with species of fig, cinnamon, fan-palm (*Sabal*), oak, yew, cypress, laurel, lime, senna, and many more. Crocodilian forms still haunted the waters, and have left their bones with those of sea-snakes and turtles and of the tapirs and other denizens of the land, which still, as in the time of the London Clay, continued to be washed out to sea. Among these strata we now find one of the most typical organisms of the Eocene rocks of the Mediterranean basin, a foraminifer termed *Nummulites* (*N. levigata*, *N. scabra*, *N. varidaria*). Characteristic fossils are *Volata athleta*, *V. lucatrina*, *Murex asper*, *Fusus longævus*, *Cardita planicosta*, and *Chama squamosa*.

Upper.—The strata of this division of the English Eocene formations are entirely confined to Hampshire and the Isle of Wight. They consist of sands, clays, marls, and lime-stones, in thin-bedded alternations. These strata were accumulated partly in the sea, partly in brackish, and partly in fresh water. They were hence named by Edward Forbes the fluvi-marine series. Among the marine fossils are—*Fusus porrectus*, *Oliva Branderi*, *Natica labellata*, *Ostrea califera*, and *Nummulites levigata*. The genera *Cerithium*, *Potamomya*, *Paludina*, *Planorbis*, *Limæa*, and *Cyclas* are abundant, showing the brackish and fresh-water conditions in which many of the strata were deposited. Remains of turtles, snakes, crocodiles, and alligators continue to occur in these Upper Eocene beds. With these are found the bones of several very characteristic mammals also met with in the Paris basin,—the three-toed *Palæotherium*, resembling the living tapir; *Anoplotherium*, a more graceful

animal with long tail, and two-toed feet, forming a kind of intermediate type between a hog and a deer or antelope, *Dickobune*, allied to the last named; also *Dichodon*, *Hypotaenium*, *Cheropotanum*, *Hyænodon*, &c. The top of the Eocene series in the Isle of Wight has been removed by denudation, so that we have no evidence in Britain of what took place after the close of the Eocene period.

CONTINENTAL EUROPE.—Geologists on the continent of Europe, finding it impossible to carry out the principle of percentage of recent species, as originally formulated by Lyell in his terminology of the Tertiary series, have made various modifications of this nomenclature. By some the three terms Eocene, Miocene, and Pliocene are retained, but, following Beyrich, they subdivide the Miocene into two, keeping that term for the upper half and calling the lower Oligocene, which corresponds with Lyell's Lower Miocene. Others would consider the whole Tertiary and post-Tertiary series as divisible into three groups, the Eocene or Older Tertiary, corresponding pretty closely to the Lyellian use of the term, the Neogene or Younger Tertiary, embracing both Miocene and Pliocene, and the Diluvial and Alluvial.

In the Paris basin the Eocene formations assume a somewhat different type from that which they present in England, though the occurrence of a number of the same species of fossils in both allows of their being paralleled in a general way. The lower Eocene consists there of sand and clay answering in lithological character to the Thanet Sand and Plastic Clay of the London basin. The common species in that basin (*Ostrea Deltoidea*) occurs there in great numbers, while the brackish water-beds contain some of the common species at Woolwich, such as *Cyrena cuneiformis* and *Melanus virgatus*. Beds of lignite occur in this division, likewise bones of *Coryphodon*, *Eocœnus*, *Viverra gigantea*, and the bird *Gastornis*. The Middle Eocene is made up of the characteristic "Calcaire grossier"—a mass of limestone, sometimes tender and crumbling, in other places so compact as to be largely quarried as a building stone. Some portions are entirely composed of minute foraminifera (micritic limestone). Among the characteristic fossils of this division are *Mammuthus*, *Coryphodon giganteus*, with bones of *Dickobune*, *Lophodon*, *Palæotherium*, &c. The Upper Eocene consists of sand (Sables muqueux) overlaid by the great gypsum and gypseous marl group of Montmartre. This is the deposit from which so many of the mammals of the Eocene period have been recovered. It is divided into three zones, and among its fossils are upwards of 50 species of quadrupeds, including many Palæotheres, Anoplotheres, Palæopliotheres, with *Xiphodon*, *Dickobune*, *Adapis*, *Cheropotanum*, *Myocœus*, *Civus Parisiensis*, *Viverra Parisiensis*, *Fespertilio*, *Didelphis viverræ*, and about 17 species of birds.

The Eocene formations of the north-west of Europe occupy but a few detached basins, and consist for the most part of soft clays, sands, marls, and thin limestones. They were laid down partly in estuaries, rivers, or lakes, partly in shallow seas near land. They contain abundantly the vegetation, with some remains of the quadrupeds and birds, of that land, and show that still in older Tertiary times, as during the long Palæozoic and Secondary ages, the chief axis of land lay to the north-west. But when we turn to the corresponding formations in central and southern Europe, they present a totally different aspect. In the first place, they at once impress us with the idea of their antiquity, for they consist chiefly of massive, hard, crystalline, and sometimes even marble-like limestones, which suggest some of the Palæozoic rocks rather than those of so modern a date as the London Clay and Calcaire Grossier. Again, instead of being confined to a few local basins, they cover an enormous geographical area and play a notable part in the structure of some of the great mountain chains of the globe. Crowded as they are with nummulites, they must have been deposited not in estuaries and shallow bays but in a wide and clear sea, which, traced by the sea of these limestones, must have ranged across the whole of the south of Europe and north of Africa, through Greece, Turkey, Asia Minor, and the heat of Asia, to the far shores of China and Japan. Since the time when this wide channel connected the Atlantic and the Pacific across the heart of the Old World, the great mountain ranges of the Pyrenees, Alps, Apennines, Carpathians, and of Central Asia, have been upheaved to their present altitude. Some of the prominent peaks along their flanks consist of the hardened and crumpled calcareous mud of the Eocene sea.

In the northern and southern Alps the Eocene formations consist of nummulitic limestone—a grey, yellow, sometimes roddish compact rock, usually containing and often made up of nummulites; nummulitic sandstone, Vienna sandstone—an enormous mass of arenaceous rock almost destitute of organic remains, and referred

partly to the Cretaceous and partly to the Eocene series, and Flysch—a massive development of dark shales or schists, sandstones, and argillaceous limestone, sometimes charged with the remains of furoids and (at Matt, Glarus) of fish. The nummulitic series of southern Europe is divided into zones characterized by fossils, and brought into a kind of broad parallelism with the subdivisions of the English and French Eocene basins. In the eastern Alps, near Vienna and elsewhere, some of the nummulitic sandstones contain enormous blocks of granite, gneiss, and other crystalline rocks, which are believed to have been ice-bones, and therefore to prove the existence of Alpine glaciers even in Eocene times. These mountains already existed, as it were, in embryo, even far back in the Secondary and Palæozoic ages. During the later part of the Eocene period they seem to have been clothed with an abundant flora, among which the fan-palm, *Balanus*, *Zygandra*, and other plants remain one of the living vegetation of tropical America, the East Indies, and Australia. Out of these plants the important coal-seams of Harz in Tyrol were formed.

MIocene.

According to the original nomenclature proposed by Lyell, this subdivision of the Tertiary series was meant to include those strata in which 17 per cent. or thereabouts of the shells belong to still living species. As the system of nomenclature was adopted at a time when our knowledge both of living and fossil species was still very defective, it could not but require modification with the progress of science. Some strata, classed at one time as Miocene from their proportion of recent forms, might, on more extended research, prove to contain a much larger percentage, and therefore to be referable to a later part of the Tertiary series. The term, however, is used as a convenient and long-established designation for a series of strata younger than the Eocene, which they seem to have succeeded, though in some parts of the European area after enormous geographical changes.

GREAT BRITAIN.—Miocene formations, in the ordinary sense of the term, are almost entirely absent from the British Islands. In Devonshire, at Bovey Tracey, a small but interesting group of sand, clay, and lignite beds, from 200 to 300 feet thick, lies between the granite of Dartmoor and the Greensand hills, in what was evidently the hollow of a Miocene lake. From these beds Hoer of Zurich, who has thrown so much light on the Miocene flora of both the Old World and the New, has described about 50 species of plants, which, he says, place this Devonshire group of strata on the same geological horizon with some part of the Lower Miocene formations of Switzerland. Among the species are a number of ferns (*Lastrea striata*, *Pecopteris ligustrum*, &c.); some conifers, particularly a *Wellingtonia* called the *Sequoia Contissa*, the debris of which forms one of the lignite beds; a few grasses, water-lilies, and a palm. Leaves of oaks, figs, laurels, willows, and seeds of grapes have also been detected—the whole vegetation implying a subtropical climate. In the north of Ireland lies a great plateau of basalt, presenting along the coast of Antrim a magnificent range of mural escarpments. The basalt-beds mark successive outpourings of lava, which took place on a prodigious scale from the Antrim region northwards through the Western Islands and the Farø Islands into Iceland, and even far up into Arctic Greenland. In Ireland the basalts attain a maximum thickness of 900 feet, in Mull about 3000 feet. They are associated with tuffs, pitchstones, trachytes, and granitoid rocks, which mark the position of the main vents of eruption. It is evident that long-continued and vigorous volcanic action took place in these north-western regions. The geological date of this activity can be approximately fixed by the fossil plants here and there to be found in leaf-beds between the sheets of basalt. They agree generally with species found in the Older Miocene beds of Switzerland; and hence the date of this marked volcanic era in the north-west of Europe and in Greenland is placed in the older part of the

Miocene period. With these exceptions there are no Miocene rocks in Britain.

CONTINENTAL EUROPE.—The records of the Miocene period in Europe bring before us a scene very different from that which the region presented during the Eocene ages. The least amount of change took place in the north-west and north. It consisted chiefly in the upraising of the floor of the shallow sea which had stretched eastwards across the north of France, and the formation of numerous fresh-water lakes, lagoons, and morasses. But over the Alpine region a vast revolution took place. The Eocene sea had its bed elevated, and the Alps rose many thousand feet above their previous height, carrying up on their flanks the hardened, upturned, crumpled, and crystallized nummulite limestone. These vast corrugations of the earth's crust were general over the whole globe about the same geological period. Subterranean movements appear to have continued during Miocene times in the Alpine area, large lake-basins were formed over a great part of what is now Switzerland, and in these the deposits of the period took place. Hence the Miocene formations of Europe are in great measure of lacustrine and terrestrial formation. The sea, however, was allowed to pass across the south of France between the central axis and the Pyrenees. It likewise covered a wide area in eastern Europe, sweeping far up into the Vienna basin and the foot of the Austrian Alps. Traces of the occasional presence of the sea can likewise be followed across Belgium and North Germany, and even on the south side of the Eifel and Westphalian high grounds in the basin of Mainz.

In France, on the north side of the axis of old rocks, the upper parts of the Eocene series are covered by certain marls, clays, and limestones, containing *Ostrea cyathula*, and passing up into the thick sandstone of Fontainebleau, well known for its picturesque scenery. These are considered as the base of the Miocene (or Oligocene) series. They contain *Fusus elongatus*, *Aporrhais speciosa*, *Pecten obsoletus*, *Cyrena cuneata*, *Cerithium phidippi*, &c. They are succeeded by some fresh-water limestones (Calcaire de Beauce) full of *Paludina*, *Planorbis*, *Lymnaea*, and *Helix*. These strata show very instructively the gradual shallowing of the sea in the north of France, and its conversion into fresh-water lakes and land. Further to the south a subsequent depression took place, in which the shelly sands and marls (limons) of Bourgue were accumulated. These strata lie in scattered patches, and seldom exceed 60 feet in thickness. They contain chiefly marine shells (*Cypraea*, *Ocenebra*, *Mitra*, *Terebra*, *Trocholaria*, *Conus*, &c.), also remains of the *Dicobovine* and *Chamopotamus*, with some of the huge early pachyderms, *Mastodon*, *Dinotherium*, rhinoceros, hippopotamus, and species of dolphin, moose, &c.

In North Germany the older Miocene rocks are marine where they pass westwards into the Belgian area, but as they are followed southwards they bear evidence of increasing proximity to land, till at last they contain abundant seams of lignite, and hence have been termed the Brown-coal series. They appear to underlie most of the great North German plain, on the south side of which they rise up into the Rhine valley, Thuringia, Saxony, and Silesia. The Brown-coal series consists of sandstones, conglomerates, and clays, with leaf-beds and seams of lignite. The last, which have been largely worked as fuel, are mainly composed of remains of conifers, (*Taxites*, *Taxozylon*, *Cupressinoxylon*, *Sequoia*), but with them are associated, in the neighbouring strata, leaves and other fragments of oak, beech, maple, fig, laurel, gumwood, magnolia, sassafras, palmettes, &c. These strata are overlaid by marine beds containing *Ostrea*, *Cardita*, *Planorbina*, *Voluta*, and numerous corals. The subterranean movements above referred to as having long affected the Alpine region were felt likewise in North Germany, for we find these marine beds succeeded by a second lignite formation, seen at Grosser Hübenecken, on the eastern horn of the Gulf of Dantzig. But this could only have been a local uplift, for marine sands and clays are next found with a wide diffusion over the plains of northern Germany.

Nowhere in Europe do the Miocene formations play so important a part in the scenery of the land, or present on the whole so interesting and full a picture of the state of Europe when they were deposited, as in Switzerland. Rising into massive mountains, as in the well-known Rigi and Rossberg, they attain a thickness of more than 6000 feet. While they include indications of the presence of

the sea, they have preserved with marvellous perfection a large number of the plants which clothed the Alps, and of the insects which flitted through the woodlands. They are termed "Molasse" by the Swiss geologists, and have been divided into the following groups:—

Upper fresh-water Molasse and brown-coal, consisting of sandstones, marls, and limestones, with a few lignite-seams and fresh-water shells, and including the remarkable group of plant and insect-bearing beds of Oeningen.

Upper marine Molasse (Helvetic stage)—sandstones and calcareous conglomerates, with 37 per cent of shells, which are to be found living partly in the Mediterranean, and partly in tropical seas.

Lower fresh-water Molasse (Mainz stage)—sandstones with abundant remains of terrestrial vegetation, and containing also an intercalated marine band with *Cerithium*, *Fusus*, &c.

Lower brown-coal or red Molasse (Aquitanian stage)—the most massive member of the whole series, consisting of red sandstones, marls, and conglomerates (Nagelfluh), resting upon variegated red marls. It contains seams of lignite, and a vast abundance of the remains of terrestrial vegetation.

Lower marine Molasse (Tongian stage)—sandstone containing marine and blackish-water shells, among which is the *Ostrea cyathula*, above mentioned as a characteristic shell, at the base of the Miocene series in the north of France.

By far the larger portion of these strata is of lacustrine origin. They must have been formed in a large lake, the area of which probably underwent gradual subsidence during the period of deposition, so that the sea gained occasional admission into it. We may form some idea of the importance of the lake from the fact already stated, that the deposits formed in its waters are upwards of 8000 feet thick. Thanks to the untiring labours of Professor Heer, we know more of the vegetation of the mountains round the lake than we do of that of any other ancient geological period. The woods were marked by the predominance of an arborescent vegetation, among which evergreen forms were conspicuous, the whole having a decidedly American aspect. Among the plants were palms of American type, the Californian coniferous genus *Sequoia*, a great variety of maples, oaks, hornbeams, poplars, poplars, willows, laurels, evergreen oaks, with vines, clematis, cypresses, and many more. In the Oeningen beds, so gently have the leaves, flowers, and fruits fallen, and so well have they been preserved, that we may actually trace the alternation of the seasons by the succession of different conditions of the plants. Selecting 482 of those plants which admit of comparison, Heer remarks that 131 might be referred to a temperate, 266 to a sub-tropical, and 85 to a tropical zone. American types are most frequent among them; European types stand next in number, followed in order of abundance by Asiatic, African, and Australian. Great numbers of insects (between 800 and 900 species) have been obtained from Oeningen. Judging from the proportions of species found there, the total insect fauna may be presumed to have been then richer in some respects than it now is in any part of Europe. The wood-beetles were specially numerous and large. Nor did the large animals of the land escape preservation in the silt of the lake. We know, from bones found in the Molasse, that among the inhabitants of that land were species of tapir, mastodon, rhinoceros, and deer. The woods were haunted by musk-deer, apes, opossums, three-toed horses, and some of the strange, long-extinct *Tertiary* ruminants, akin to those of Eocene times. There were also fogs, lands, snakes, scorpions, hares, leopards, and a number of small carnivores. On the lake the huge *Dinotherium* floated, mooring himself perhaps to its banks by the two strong tusks in his under jaws. The waters were likewise tenanted by numerous fishes (of which 32 species have been described, all save one referable to existing genera), crocodiles, and chelonians.

Contemporaneously with the existence of the great Swiss Miocene lake, one or more large sheets of fresh water lay in the heart of France. In these basins a series of marls and limestones (1500 feet thick) accumulated, from which have been obtained the remains of nearly 100 species of mammals, including some plerotheres, like those of the Paris Eocene basin, a few genera found also in the Lower Miocene beds of Mainz, crocodiles, snakes, and birds. This water basin appears to have been destroyed by volcanic explosions, which afterwards poured out the great sheets of lava, and formed the numerous cones and *pyres* so conspicuous on the plateau of Auvergne.

The sea which during the later part of the Miocene period stretched across the south of France ran also up the present valley of the Danube to the foot of the Alps and the high grounds of Bohemia and Moravia. In this wide eastern bay or Vienna basin a series of deposits was laid down, which have been grouped in four divisions,—the two lower classed as Miocene, and the two upper as Pliocene. The lowest group (Mediterranean stage or Marine Tegel) has yielded more than 1000 species of mollusca (*Conus*, *Anchilina*, *Pyrula*, *Murex*, *Cerithium*, &c.), with remains of *Mastodon*, *Dino-*

the town, and other mammals. The second group (Sarmatian stage) consists of brackish-water beds showing the partial uprise of the bottom of the Vienna basin. It contains *Cerithium*, *Paludina*, *Rissoa*, with bones of dolphins, seals, turtles, and fish. The two uppermost divisions (Congeria stage and Belvedere stage), referred to the Pliocene series, are fresh-water formations, showing the final freshening and disappearance of the Miocene sea in the south-east of Europe.

In Styria and Carinthia the lower Aquitanian or Mediterranean stage bears witness in its plants and ligules to the proximity of land during its formation, while its shells are of fresh and brackish water genera. It has subsequently been upheaved, and the later Miocene strata lie unconformably on its edges. The subterranean movements east of the Alps culminated in the outpouring of enormous sheets of trachyte, andesite, porphyry, and basalt in Hungary and along the flanks of the Carpathian chain into Transylvania. In Croatia the older Miocene marls, with their abundant land-plants, insects, &c., contain two beds of sulphur (the upper 4 to 16 inches thick, the under 10 to 15 inches), which have been worked at Radoboj. At Hraštevog, Buchberg and elsewhere, coal is worked in the Aquitanian stage in a bed sometimes 65 feet thick. In Transylvania, and along the base of the Carpathian mountains, extensive masses of rock-salt and gypsum are interstratified in the Tertiary formations. The largest of these, that of Parajd, has a maximum length of about 2500 yards, a breadth of 1800 yards, and a depth nearly 200 yards, and is estimated to contain 3500 millions of cubic feet of salt.

GREENLAND.—One of the most remarkable geological discoveries of recent times has been that of Miocene plant beds in North Greenland. Heer has described a flora extending at least up to 70° N. lat., containing 137 species, of which 46 are found also in the central European Miocene basins. More than half of the plants are trees, including 30 species of conifers (*Sequoia*, *Thuopsis*, *Salisburia*, &c.), besides beeches, oaks, planes, poplars, maples, walnuts, limes, magnolias, and many more. These plants grew on the spot, for their fruits in various stages of growth have been obtained from the beds. From Spitzbergen (78° 56' N. lat.) 136 species of fossil plants have been named by Heer. But the latest English Arctic expedition brought to light a bed of coal, black and lustrous like one of the Paleozoic fuels, from 81° 45' lat. It is from 25 to 30 feet thick, and is covered by black shales and sandstones full of land-plants. Heer notices 26 species, 18 of which had already been found in the Arctic Miocene zone. As in Spitzbergen, the conifers are most numerous (pines, firs, spruces, and cypresses), but there occur also the arctic poplar, two species of birch, two of hazel, an elm, and a viburnum. In addition to these terrestrial trees and shrubs the stagnant waters of the time bore water-lilies, while their banks were clothed with reeds and sedges. When we remember that this vegetation grew luxuriantly within 8° 15' of the North Pole, in a region which is now in darkness for half of the year, and is almost continuously buried under snow and ice, we can realize the difficulty of the problem in the distribution of climate which these facts present to the geologist.

PLIOCENE.

GREAT BRITAIN.—The Miocene period seems to have passed away without any notable portion of the British Islands being depressed under the sea. Save the great outpouring of lava in the north-west, and the rise of hundreds of "dykes" of basalt along cracks of the crust in the north of England and throughout Scotland, the area of Britain seems to have remained as a part of the mainland of Europe, little affected by the subterranean movements which, as we have seen, were so potent among the Alps and in eastern Europe. At length the south-eastern counties began to subside, and on their submerged surface some sandbanks and shelly deposits were laid down, very much as similar accumulations now take place at the bottom of the North Sea. These formations are termed the Crag, and are subdivided, according to their proportion of living species of shells, into the following groups:—

Chillesford beds	{ Chillesford Clay 1 to 8 ft
	{ Chillesford Sand with shells 5 " 8 "
Norwich (Fluvio-marine, mammaliferous) Crag	5 " 10 "
Red Crag	25 "
White (Suffolk, coralline) Crag	40 " 60 "

The White Crag consists of shelly sands and marls. It contains 316 species of shells, of which 84 per cent. are still living. Among these are *Terebratula grandis*, *Lingula Dumortieri*, *Pecten opercularis*, *Pholadomya histerna*, *Pyrgula reticulata*. The name coralline was given to the formation from the immense number of coral-like polyzoa which it contains, no fewer than 130 species having been described. The Red Crag is also a thin and local formation, consisting of a dark-red or brown ferruginous shelly sand. Of its mollusks, 92 per cent are believed to be still living species, and, out of 25 species of corals, 14 are still natives of British seas. Some of the typical shells of this subdivision are *Trophon antiquum* (*Fusus contrarius*), *Volva Lamberti*, *Purpura tetragona*, *Pecten opercularis*, *Pectunculus glyceris*, and *Cyprina rustica*. Numerous mammalian remains have been obtained from these sands, including bones of *Mastodon Arvernensis* and *M. taproideus*, *Elephas meridionalis*, *Rhinoceros Schlegelii macheri*, *Tapirus priscus*, *Sus antiquus*, *Equus phidicus*, *Hipparion*, *Hyena antiqua*, *Felis pardoides*, and *Cervus anoceros*. The Norwich or Fluvio-marine or Mammaliferous Crag consists of a few feet of shelly sand and gravel, containing, so far as known, 139 species of shells, of which 93 per cent. are still living. About 20 of the species are land or fresh-water shells. The name of mammaliferous was given from the large number of bones, chiefly of extinct species of elephant, recovered from this deposit. These fossils comprise *Mastodon Arvernensis*, *Elephas meridionalis*, *E. antiquus*, a hippopotamus, horse, and deer, likewise the living species of otter and beaver. One interesting feature in this formation is the decided mixture in it of northern species of shells, such as *Rhynchonella pectata*, *Scaloria Granlandica*, and *Astarte borealis*. These may be regarded as the forerunners of the great invasion of Arctic plants and animals which, in the beginning of the Quaternary ages, came southward into Europe, together with the severe climate of the north. The Chillesford beds occur likewise as a thin local deposit in Suffolk and Norfolk. Of the shells which they contain, about two-thirds still live in Arctic waters. It is evident that, in these fragmentary accumulations of the Crag series, we have merely the remnants of some thin sheets of shelly sands and gravels laid down in the shallow waters of the North Sea, while that great lowering of the European climate was beginning which culminated in the succeeding or Glacial period.

CONTINENTAL EUROPE.—Marine strata, sometimes of considerable thickness, were laid down over different portions of the European area during the Pliocene period. The most extensive of these occur in Italy and Sicily, in the latter island they have since been upheaved to a height of 3000 feet above the sea. They have likewise been used into the chain of heights flanking the Apennine Mountains, where they are known as the Subapennine series. In the shoal waters and estuaries of that ancient Italy some of the same huge mammals lived as we contemporaneously denizens of England,—the Auvorgne mastodon *Ixodonos Elruscus*, *Elephas meridionalis*, *Hippopotamus major*, with bears and hyenas.

Eastwards we obtain evidence of the gradual exclusion of the sea from the areas of the European continent which it had covered during the Miocene period. The Congeria stage (above referred to) of the Vienna basin brings before us the picture of an isolated gulf gradually freshening by the impinging of rivers like the modern Caspian, but with bays nearly cut off from the main body of water, and undergoing so copious an evaporation without counterbalancing inflow that their salt was deposited over the bottom as in the Karaboghaz of the Caspian (*ante*, p. 279).

TERTIARY SERIES OF NORTH AMERICA.

Tertiary formations of marine origin extend in a strip of low land along the Atlantic border of the United States,

from the coast of New Jersey southward round the margin of the Gulf of Mexico, whence they run up the valley of the Mississippi to beyond the mouth of the Ohio. On the western sea-board they also occur in the coast ranges of California and Oregon, where they sometimes have a thickness of 3000 or 4000 feet, and reach a height of 3000 feet above the sea. Over the Rocky Mountain region Tertiary strata cover an extensive area, but are chiefly of fresh-water origin, though containing marine interstratifications. The following are the subdivisions into which they have been grouped, together with their supposed European equivalents —

4. Sanitoi series = Pliocene.
3. Yorktown, „ = Miocene, with perhaps part of Pliocene.
2. Alabama „ = Middle and Upper Eocene.
1. Lignite „ = Lower Eocene.

1. *Lignite*.—As already mentioned, it is still matter of dispute whether this formation should not be included wholly or in large measure in the Cretaceous system below. It consists mainly of lacustrine strata, with occasional brackish water and marine bands. Its name is derived from the beds of fossil fuel which it contains. The mollusca in some of the shell-bearing beds comprise species of *Inoceramus*, *Anchusia*, *Gyrodes*, *Cyrtium*, *Cyrena*, *McClampus*, *Ostrea*, and *Anomia*. Other strata contain the modern lacustrine and fluviatile genera *Physa*, *Faiata*, *Cyrena*, *Corbula*, and *Unio*. An abundant terrestrial flora has been distinguished from the Lignite strata. It resembles in many respects the present flora of North America, comprising as it does species of oak, poplar, maple, elm, dogwood, beech, hickory, ilex, plane, fig, cinnamon, laurel, magnolia, smilax, thuya, sequoia, and several palms. A few of the species are common to the Middle Tertiary flora of Europe, and a number of them have been met with in the Tertiary beds of the Arctic regions. Some of the seams of vegetable matter are true bituminous coals and even anthracites.

It was stated in the account of the North American Cretaceous rocks that considerable difference of opinion exists as to the line to be drawn between these rocks and those of Tertiary age. According to Cope, the Vertebrate remains of the Lignite series bind it indissolubly to the Mesozoic formations. Lesquereux, on the other hand, insists that the vegetation is unequivocally Tertiary. The former writer, admitting the force of the evidence furnished by the fossil plants, concludes, that “there is no alternative but to accept the result, that a Tertiary flora was contemporaneous with a Cretaceous fauna, establishing an uninterrupted succession of life across what is generally regarded as one of the greatest breaks in geologic time.” The Lignite series was disturbed along the Rocky Mountain region before the deposition of the succeeding Tertiary formations, for these lie unconformably upon it. So great have been the changes in some regions that the strata have assumed the character of hard slates like those of Paleozoic date, if indeed they have not become in California thoroughly crystalline masses.

2. *Alabama Group*.—The strata included in this group are believed to represent the Middle and Upper Eocene of Europe. As their name implies, they are well developed in the State of Alabama, where they consist of two sub-groups,—(1) the Clayborne beds—clays, marls, limestones, lignite, and sands, and (2) the Vicksburg beds—lignite clays, limestones, and marls,—the whole attaining a thickness of nearly 250 feet. But the strata thicken into South Carolina. Towards the west the marine fossils give place to land-beds and lignites. In the Green River basin the strata attain a thickness of more than 2000 feet. In the disturbed Lignite group, and containing beds of coal, with remains of fish and of tapirid pachyderms. The fossils of the Alabama group in the eastern States comprise numerous sharks, some of which are specifically, and more are generically, the same as some of the English Eocene forms, such as *Lamna elegans*, and *Carcharodon megalodon*; also bones of several crocodiles and snakes. In the lacustrine and fluviatile deposits of the west there have been found also the remains of several birds, and a large number of mammals, including marsupials, numerous representatives of the tapirs, with double pairs of nasal horns, an early form of horse (*Orokypus*) not larger than a fox, and with four toes in the fore foot, rodents, insectivores, bats, carnivores, and a number of forms allied to the living lemurs and marmosets. The richness of this fauna is remarkable, particularly in the mammals.

3. *Yorktown Group*.—Under this name are classed strata of sand and clay, which extend over a large area in the seaward part of the eastern States. Their organic remains (comprising mollusks, with remains of sharks, seals, walrus, whales, &c.) show them to have been chiefly laid down in a shallow sea in Miocene time. Westward, in the Upper Missouri region, and across the Rocky Mountains into California and Oregon, strata assigned to the same geological period were laid down in great lakes, and attain thicknesses of 1000 to 4000 or 5000 feet. The organic remains of these ancient lakes embrace examples of three-toed horses (*Anchitherium*), of horned tapir-like

animals (*Titanotherium*), of forms related to the hog, rhinoceros, camel, lama, deer, musk-ox, hare, squirrel, beaver, hyena, wolf, panther, and tiger. The intermediate types indicated by Cuvier among the Paris Tertiary beds have been greatly increased from the American Tertiary groups by the researches of Marsh and Leidy.

4. *Sanitoi Group* or *Pliocene*.—In the Carolina States beds of loam, clay, or sand, lying in hollows of the older Tertiary deposits, and containing from 40 to 60 per cent. of living marine shells, are referred to the Pliocene age. In the Upper Missouri region, the Yorktown group is overlaid by other fresh-water beds, which are believed to be Pliocene. These strata contain land and fresh-water shells, probably of existing species. But their most remarkable organic remains are the mammalia, which continue the wonderful series in the strata underneath. Dana thus summarizes the facts — “Leidy has determined a large number of Pliocene mammals, all now extinct. They include three species of camel (*Procamelus*); a rhinoceros as large as the Indian species, a mastodon smaller than *M. Americus*, L., of the Quaternary; an elephant (*E. Americus*), occurring also in the Quaternary; four or five species of the horse family, one of which was closely like the modern horse; a species of deer (*Corvus Warreni*, L.); others near the musk-deer of Asia; species of *Meleoides*, allied to *Oreodon* (a genus intermediate between deer, camel, and hog); a wolf larger than any living species, a small fox, a tiger (*Felis augustus*, L.) as large as the Bengal tiger, besides other canivores, a small beaver, a porcupine. The collection of animals has a strikingly Oriental character, except in the preponderance of herbivores.”

V. POST-TERTIARY OR QUATERNARY

Under this division are included the various superficial deposits in which all the mollusca are of salt living species. It is usually subdivided into two series—(1) an older group of deposits in which many of the mammals are of extinct species,—to this group the names of Pleistocene, Post-Pliocene, or Diluvial have been given; and (2) a later series, wherein the mammals are all of still living species, to which the name of Recent or Alluvial has been assigned. These subdivisions, however, are confessedly very artificial, and it is often exceedingly difficult to draw any line between them.

In Europe and North America a tolerably sharp demarcation can usually be made between the Pliocene formations and those now to be described. The Crag deposits of the south-east of England show traces of a gradual lowering of the temperature during later Pliocene times. This change of climate continued to augment until at last thoroughly arctic conditions prevailed, under which the oldest of the Post-Tertiary or Pleistocene deposits were accumulated.

It is hardly possible to arrange these deposits in a strict chronological order, because we have no means of deciding, in many cases, their relative antiquity. The following table is rather an enumeration of the more important of them than an arrangement in their exact sequence:—

Recent	River alluvia, peat mosses, lake deposits, blown sand, marine deposits, raised beaches
	Duck-earth, valley-gravels, old marine terraces, cavern-deposits
Pleistocene or Glacial.	Moraine-steps, Kame or Esker series, Clyde-belt, Upper Boulder clays, Inter-glacial beds, Lower Till, ice-worn rock-surfaces
	Pre-glacial forests and land surface

PLEISTOCENE OR GLACIAL.

Under the name of the Glacial Period or Ice Age, a remarkable geological episode in the history of the northern hemisphere is denoted. We have seen in the foregoing section on the Crag deposits that there is evidence of a gradual refrigeration of the climate at the close of the Tertiary ages. This change of temperature affected the higher latitudes alike of the Old and the New World. It reached such a height that the whole of the north of Europe was buried under snow and ice, extending southwards even as far as Saxony. The Alps and Pyrenees were loaded with vast snow-fields, from which enormous glaciers descended into the plains, overriding ranges of minor hills on their way. The greater portion of Britain was similarly ice-covered.

The effect of the movement of the ice was necessarily to remove the soils and superficial deposits of the land surface. Hence in the areas of country so affected, the ground having been scraped and smoothed, the glacial accumulations laid down upon it rest abruptly, and without any connexion, on whatever underlies them. Considerable local differences may be observed in the nature and succession of the different deposits of the glacial period, as they are traced from district to district. It is hardly possible to determine, in some cases, whether certain portions of the series are coeval or belong to different epochs. But the following are the leading facts which have been established for the North-European area. First, there was a gradual increase of the cold, though with warm intervals, until the conditions of modern North Greenland extended as far south as Middlesex, Wales, the south-west of Ireland, and 50° N. lat. in central Europe. This was the culmination of the Glacial period. Then followed a considerable depression of the land and the spread of cold arctic water over the submerged tracts, with abundant floating ice; next came a re-elevation, with renewed augmentation of the snow-fields and glaciers. Very gradually, and after intervals of increase and diminution, the ice retired towards the north, and with it the arctic flora and fauna that had peopled the European plains. The existing snow-fields, and glaciers of the Pyrenees, Switzerland, and Norway are remnants of the great ice-sheets of the glacial period, while the arctic plants of the mountains are relics of the northern vegetation which was universal from Norway to Spain.

Ice-worn Rocks.—Beginning at the base of the deposits from which this interesting history is compiled, we find the solid rocks over the whole of northern Europe to present the characteristic smoothed flowing outlines which can be produced only by the grinding action of land-ice (*ante*, p. 282). Where they have been long exposed, this peculiar surface is apt to be effaced by the disintegrating action of the weather, though it retains its hold with extraordinary pertinacity. Along the fjords of Norway and the sea-lochs of the west of Scotland, it may be seen slipping into the water, smooth, bare, polished, and grooved as if the ice had only recently retreated. But where the protecting cover of clay or other superficial deposits has been newly removed, the peculiar ice-worn surface is as fresh as that by the side of a modern glacier. Observations of the directions of the striae have shown that on the whole these markings diverge from the main masses of high ground. In Scandinavia they run westwards and south-westwards on the Norwegian coasts, and eastwards or south-eastwards across the lower grounds of Sweden. When the ice descended into the basin of the Baltic and the plains of northern Germany, it moved southwards and south-westwards, but seems to have slightly changed its direction in different areas and at different times. Its movements can be made out partly from the striae on the solid rock, but more generally from the glacial drift which it has left behind. Thus it can be shown to have moved down the Baltic into the North Sea. At Berlin its movement must have been from east to west. But at Leipsic, as recently ascertained by Credner, it came from N.N.W. to S.S.E., being doubtless set off in that direction by the high grounds of the Harz mountains. Its southern limit can be traced with tolerable clearness from Jevernaar in Holland eastwards across the Rhine valley, along the base of the Westphalian hills, round the projecting promontory of the Harz, and then southwards through Saxony to the roots of the Erzgebirge. Passing next south-eastwards along the flanks of the Riesen and Sudeten chain, it sweeps across Poland into Russia, circling round by Kieff, and northwards by Nijni Novgorod towards the Uralis.

It has been estimated that, excluding Finland, Scandinavia, and the British Isles, the ice must have covered not

less than 1,700,000 square kilometres of the present lowlands of Europe. Its influence on the solid rocks over which it passed has not been everywhere equal. Over much of the north German plain, indeed, the rocks are concealed under drift. But in the more undulating hilly ground, particularly in the north and north-west, the ice has effected the most extraordinary abrasion. It is hardly possible, indeed, to describe adequately in words these regions of most intense glaciation. The old gneiss of Norway and Sutherlandshire, for example, has been so eroded, smoothed, and polished, that it stands up in endless rounded hummocks, many of them still smooth and flowing like dolphins' backs, with little pools, tarns, and larger lakes lying between them. Seen from a height the ground appears like a billowy sea of cold grey stone. The lakes, every one of them lying in a hollow of erosion, seem scattered broadcast over the landscape. So enduring is the rock, that even after the lapse of so long an interval, it retains its ice-worn aspect almost as unpurged as if the work of the glacier had been done only a few generations since.

Some idea of the massiveness of the ice-sheet is obtainable from a consideration of the way in which the striae run across important hill ranges, and athwart what might seem to be their natural direction. Whilst there was a general southward movement from the great snow-fields of Scandinavia, the high grounds of Britain were important enough to have their own independent ice, which, as the striae show, radiated outward, some of it passing westwards into the Atlantic and some of it eastward into the North Sea. So thick must it have been as it moved off the Scottish Highlands that it went across the broad plains of Perthshire, filling them up to a depth of at least 2000 feet, and passing across the range of the Ochil Hills, which at a distance of 12 miles runs parallel with the Highland mountains, and reaches a height of 2352 feet. In such cases it has been observed that the striae along the lower slopes of the hill barrier run either parallel with the trend of the ground or slant up obliquely, while those on the summits may cross the ridge at right angles to its course. This shows that there must have been a differential movement in the great ice-sheet, the lower parts, as in a river, becoming embayed, and being forced to move in a direction sometimes even at a right angle to that of the general advance. On the lower grounds, also, the striae, converging from different sides, unite at last in one general trend as the various ice-sheets must have done, as they descended from the high grounds on either side and coalesced into one common mass. This is well seen in the great central valley of Scotland. Still more marked is the deflexion of the striae in Caithness and the Orkney and Shetland Islands. In these districts the general direction of the striation is from S.S.E., which, in Caithness, is nearly at right angles to what might have been anticipated. This deflexion has been attributed to the coalescence of the ice from Norway and from the northern Highlands in the basin of the North Sea, and its subsequent progress along the resultant line into the Atlantic. But it may have been due to the fan-shaped spreading out of the vast mass of ice descending into the Moray Firth; for the striae on the south side of that inlet run E. by S., and at last S.E., on the north-east of Aberdeenshire, showing that the ice, on the one hand, turned southwards into the North Sea, until it met the N.E. stream from Kincardineshire and the valleys of the Dee and Don, while, on the other, it moved northward so as no doubt to join the Scandinavian sheet, and march with it into the Atlantic. The basin of the North Sea must have been choked up with ice in its northern parts, if not entirely. At that time England and the north-west of France were united, so that any portion of the North Sea basin not invaded by land-ice must have formed a lake,

with its outlet by the hollow through which the Strait of Dover has since been opened. It has been suggested that during such a condition of things the widespread fresh-water deposit termed Loess was formed, which covers so large a space in the lower plains of the Rhine and the north of Belgium, and appears in the valleys of the south-east of England.

The ice is computed to have been at least between 6000 and 7000 feet thick in Norway, measured from the present sea-level. From the height at which its transported debris has been observed on the Harz, it is believed to have been at least 1470 feet thick there, and to have gradually risen in elevation as one vast plateau, like that which at the present time covers the interior of Greenland. Among the Alps it attained almost incredible dimensions. The present snowfields and glaciers of these mountains, large though they are, form no more than the mere shrunken remnants of the great mantle of snow and ice which then over-spread Switzerland. In the Bernese Oberland, for example, the valleys were filled to the brim with ice, which, moving northwards, crossed the great plain, and actually overrode a part of the Jura mountains. Huge fragments of granite and other rocks from the central chain of the Alps are found high on the slopes of that range of heights.

Boulder-clay or Till.—Under this name is included the debris which accumulated and was pushed onward under the ice-sheet, the "grund-morane" or "moraine profonde" (*ante*, p. 282). All over the low grounds of North Germany, Denmark, and Holland lies a stony or earthy clay passing into sand or gravel, in which, together with locally derived debris, there is a greater or less proportion of fragments from the north. Some of the rocks of Scandinavia, Finland, and the Upper Baltic are of so distinctive a kind that they can be recognized in small pieces in the boulder-clay. Thus the peculiar syenite of Länarvig in the south of Norway has been recognized abundantly in the drift of Denmark, it occurs in that of Hamburg, and in the boulder-clay of the Holderness cliffs in Yorkshire. The well-known Rhombenporphyry of southern Norway has likewise been recognized at Holderness. Fragments of the Silurian rocks from Gotland, or from the Russian islands Dago or Oesel, have been met with as far as the north of Holland. These transported fragments, so abundant within the line of demarcation just traced, are an impressive testimony to the movements of the northern ice-sheet and floating ice.

The boulder-clay is not spread as a uniform sheet over the ground, but varies greatly in thickness and in irregularity of surface. Round the mountainous centres of dispersion it is apt to occur in long ridges or "drums" which run in the general direction of the rock-striation.

In those areas which served as independent centres of dispersion for the ice-sheet, the boulder-clay partakes largely of the local character of the rocks of each district where it occurs. Thus in Scotland the clay varies in colour and composition as it is traced from district to district. Over the Carboniferous rocks it is dark, over the red sandstones it is red, over the Silurian rocks it is fawn-coloured. The great majority of the stones also are of local origin, not always from the immediately adjacent rocks, but from points within a distance of a few miles. Evidence of transport, however, can be gathered from the stones, for they are found in almost every case to include a proportion of fragments which have come from beyond the district. The direction indicated by the percentage of travelled stones is always the same for each region. Thus, in the lower part of the valley of the Firth of Forth, while most of the fragments are from the surrounding Carboniferous formations, from 5 to 20 per cent. is found to have come eastward from the Old Red Sandstone range of the Ochil Hills—a distance of 25 or 30 miles, while 2 to 5 per cent. are

pieces of the Highland rocks, which must have come from the high grounds at least 50 miles to the north-west. The evidence of dispersion revealed by the stones in the boulder-clay harmonizes with that of the striae on the rocks. Every main mass of elevated ground in Britain seems to have caused the ice to move outward from it for a certain distance, until the stream coalesced with that descending from some other height. In Scotland the ice was massive enough to move out into the basin of the North Sea (then doubtless in great part usurped by the glaciers) until it met that which was streaming down from Scandinavia. Hence no Scandinavian blocks have ever been found in Scotland. But the Norwegian ice which crept southwards across Denmark, may once have extended across the North Sea to the Yorkshire coast, if the Scandinavian stones of Holderness were not carried on floating ice.

The stones in the boulder-clay have a characteristic form and surface. They are usually oblong, have one or more flat sides or "soles," are smoothed or polished, and have their edges worn round. Where they consist of a fine-grained enduring rock, they are almost invariably found to be striated, the striae running with the long axis of the stone. These markings are precisely similar to those on the solid rocks underneath the boulder clay, and like them have manifestly been produced by the friction of stones and grains of sand as the whole mass of debris was being steadily pushed on in one given direction by the resistless advance of the ice (*ante*, p. 282).

Interglacial Beds.—The boulder-clay is not one uniform mass of material. In a limited section, indeed, it usually appears as an unstratified mass of stiff stony clay. But it is found on further examination to be split up with various inconstant and local interstratifications. Beds of sand, gravel, fine clay, and peaty layers occur in this way in different platforms in the boulder clay. In Scotland and elsewhere these interpolated beds bear witness to intervals when the ice retired from the area, and the land, so far as uncovered, was clothed with vegetation and traversed by herds of the hairy mammoth, reindeer, and musk-ox. Hence the long glacial period must have been interrupted by episodes probably of considerable duration when a milder climate prevailed. Such an alternation of conditions is explained on the hypothesis discussed in previous pages (*ante*, pp. 218–220).

Evidence of Submergence.—After the ice had attained its greatest development, the land, which perhaps in north-western Europe stood at a higher level above the sea than it has done since, began to subside. The ice-fields were carried down below the sea-level, where they broke up and cumbered the sea with floating bergs. The heaps of loose debris which had gathered under the ice, being now exposed to waves, ground-swell, and marine currents, were thereby more or less washed down and reassorted. Coast-ice, no doubt, still formed along the shores, and was broken up into moving floes, as happens every year now in northern Greenland. The proofs of this phase of the long glacial period are contained in the sands, gravels, erratic blocks, and stratified clays which overlie the coarse older till. It is difficult to determine the extent of the submergence, for when the land rose the more elevated portions continued to be the seats of glaciers, which, moving over the surface, destroyed the deposits which would otherwise have remained as witnesses of the presence of the sea. The most satisfactory evidence is undoubtedly that supplied by beds of marine shells. These have been observed on Moel Tryfan, in North Wales, at a height of no less than 1350 feet, but as the same kind of deposits in which they occur extend to a much greater height, the submergence probably considerably exceeded the limit at which the shells occur. In Cheshire beds of shells have been met with at a height of

1200 feet. In Scotland the highest level from which they have yet been obtained is 524 feet, and in this instance they lie in one of the interstratifications in the boulder-clay. The coast of Scotland is fringed by a succession of raised beaches which, up to that at 100 feet above the present mean tide-level, are often remarkably fresh. The 100-feet terrace forms a wide plateau in the estuary of the Forth, and the 50-feet terrace is as conspicuous on the Clyde. The elevation of the land has brought up within tide-marks some of the clays deposited over the sea-floor during the time of the submergence. In the Clyde basin and some of the western fjords these clays (Clyde beds) are full of shells. Comparing the species with those of the adjacent seas, we find them to be more boreal in character; nearly the whole of the species still live in Scottish seas, though a few are extremely rare. Some of the more characteristic northern shells in these deposits are *Pecten Islandicus*, *Tellina calcarata*, *Leda truncata*, *L. lanceolata*, *Saxicava rugosa*, *Panopea Norvegica*, *Trophon clathratum*, and *Natica clausa*.

That ice continued to float about in these waters is shown by the striated stones contained in the fine clays, and by the remarkably contorted structure which these clays occasionally display. Sections may be seen where, upon perfectly undisturbed horizontal strata of clay and sand, other similar strata have been violently crumpled, while horizontal beds lie directly upon them. These contortions must have been produced by the horizontal pressure of some heavy body moving upon the originally flat beds. No doubt the agent was ice in the form of large stranding masses which were driven aground in the fjords or shallow waters where the clays accumulated. Another indication of the presence of floating ice is furnished by large boulders scattered over the country, and lying sometimes on the stratified sands and gravels, though no doubt many of the so-called erratics belong to the time of the chief glaciation.

One of the most puzzling members of the Drift is the series of sands and gravels which cover the low grounds in many places, and rise up to heights of 1000 feet and more. These deposits are sometimes spread out in undulating sheets, which, in the lower districts, seem to merge insensibly into the marine terraces and raised beaches. But they are also very commonly disposed in remarkable mounds and in ridges which run across valleys, along hill-sides, and even over watersheds. These ridges are known in Scotland as kames, in Ireland as eskers, and in Scandinavia as osar. They consist sometimes of coarse gravel or earthy detritus, but more usually of clean, well-stratified sand and gravel, the stratification towards the surface corresponding with the external slopes of the ground, in such a manner as to prove that the ridges are original forms of deposit, and not the result of the irregular erosion of a general bed of sand and gravel. Some writers have compared these features to the submarine banks formed in the pathway of tidal currents near the shore. Others have supposed them rather to be of terrestrial origin, due to the melting of the great snow-fields and glaciers, and the consequent discharge of large quantities of water over the country. But no very satisfactory explanation has yet been given.

Re-emergence.—Later Glaciers.—When the land began to rise again, the temperature all over central and northern Europe was still severe. Vast sheets of ice still held sway over the mountains, and continued to descend into the lower tracts and to go out to sea. To this period are ascribed certain terraces or "parallel-roads" which run along the sides of valleys in the Scottish Highlands. It is believed that the mass of ice descending from some of the loftier snow-fields of this time was so great as to accumulate in front of lateral valleys, and to so choke them up as to cause the water to accumulate in them and flow out in an opposite

direction by the *col* at the head. In these natural reservoirs the level at which the water stood for a time was marked by a horizontal ledge or platform due partly to erosion of the hill-side and partly to the arrest of the descending debris when it entered the water.

Every group of mountains nourished its own glaciers, even small islands, such as Arran in Scotland, had their snowfields, whence glaciers crept down into the valleys and shed their moraines. It would appear indeed that some of the northern glaciers of Scotland continued to reach the sea-level even when the land had risen to within 50 feet or less of its present elevation. On the east side of Sutherlandshire the moraines descend to the 50-feet raised beach, on the west side of the same county they come down still lower. The higher mountains of Europe still show the descendants of these later glaciers, but the ice has retreated from the lower elevations. In the Vosges the glaciers have long disappeared, but their moraines remain still fresh. In Wales, Cumberland, and the southern uplands and Highlands of Scotland, moraines, perched blocks, and *roches moutonnées* attest the abundance and persistence of the last glaciers. It is sometimes possible to trace the stages in the gradual retreat of the ice towards its parent snow-fields, for the crescent-shaped moraine mounds lie one behind another until they finally die out about the head of the valley, near what must have been the edge of the snow-field.

We know as yet very little of the fauna and flora of the land during the Glacial Period in Europe. The vegetation was doubtless in great measure the same as that of arctic Norway at the present day. The animals included the musk-ox, lemming, rein-deer, and other still living arctic forms, but included some which have become extinct, such as the hairy mammoth and woolly rhinoceros. During the milder inter-glacial periods denizens of warmer regions found their way northwards into Europe. Thus the hippopotamus haunted the rivers of the south of England. By degrees, as the climate ameliorated, the arctic vegetation was finally extirpated from the lower grounds of central and western Europe, and plants loving a milder temperature, which had doubtless been natives of Europe before the period of great cold, were enabled to reoccupy the sites whence they had been driven. On the higher mountains, where the climate is still not wholly uncongenial for them, colonies of this once general arctic flora still survive. The arctic animals have also been driven away to their northern homes, or have become wholly extinct. And thus, as imperceptibly as it began, the long and varied Ice Age came to an end as it merged into the next succeeding geological period.

RECENT OR HUMAN PERIOD.

That long succession of ages to which the name of the Glacial Period has been given shaded without abrupt change of any kind into what is termed the Human or Recent Period. Indeed it may be said with truth that the Glacial Period still exists in Europe. The snow-fields and glaciers have disappeared from Britain, but they still linger among the Pyrenees, remain in larger mass among the Alps, and spread over wide areas in northern Scandinavia. This dovetailing or overlapping of geological periods has been the rule from the beginning of time, the apparently abrupt transitions in the geological record being due to imperfections in the chronicle.

The question has often been asked whether man was coeval with the Ice Age. To give an answer, we must know within what limits the term Ice Age is used, and to what particular country or district the question refers. For it is evident that even to-day man is contemporary with the Ice Age in the Alpine valleys and in Finnmark. There can

be no doubt that he inhabited Europe after the greatest extension of the ice, but while the rivers were still larger than now from the melting snow, and flowed at higher levels.

The proofs of the existence of man in former geological periods are not to be sought for in the occurrence of his own bodily remains, as in the case of other animals. His bones are indeed now and then to be found, but in the vast majority of cases his former presence is revealed by the implements he has left behind him, formed of stone, metal, or bone. Many years ago the archaeologists of Denmark, adopting the subdivisions of the Latin poets, classified the prehistoric traces of man in three great divisions—those of (1) the Stone Age, (2) the Bronze Age, and (3) the Iron Age. There can be no doubt that, on the whole, thus has been the general order of succession. Men used stone and bone before they had discovered the use of metal. Nevertheless, the use of stone long survived the introduction of bronze and iron. In fact, in many European countries where metal has been known for many centuries, there are districts where stone implements are still employed, or where they were in use until quite recently. It is obvious also that, as there are still barbarous tribes unacquainted with the fabrication of metal, the Stone Age is not yet extinct in many parts of the world. In this instance we again see how geological periods run into each other. The nature or shape of the implement cannot therefore be always a very satisfactory proof of antiquity. We must judge of it by the circumstances under which it was found. From the fact that in north-western Europe the ruler kind of stone weapons occurs in what are certainly the older deposits, while others of more highly finished workmanship are found in later accumulations, the Stone Age has been subdivided into an early or Paleolithic and a later or Neolithic epoch. There can be no doubt, however, that the later was in great measure coeval with the age of bronze, and even to some extent of iron.

The deposits which contain the history of the human period are river-loam, river-alluvia, lake-bottoms, peat-mosses, sand dunes, and other superficial accumulations.

Most calcareous districts abound in underground tunnels and caverns which have been dissolved by the passage of water from the surface (*ante*, p. 271). In a large number of cases these cavities have communicated with the outer surface, so that terrestrial animals, including man himself, have made use of them as places of retreat, or have fallen or been washed into them. The floors of some of them are covered with loam or cave-earth, resulting from the deposit of the silt carried in the water which formerly flowed through them. Very commonly also, a deposit of stalagmite has formed from the drip of the roof. Hence any organic remains which may have found their way to these floors have been sealed up and admirably preserved.

Above the present levels of the rivers there are platforms or terraces of alluvium, sometimes to a height of 80 or 100 feet. These deposits are fragments of the river gravels and loams laid down when the streams flowed at that elevation, and therefore before the valleys were widened and deepened to their present form. River action is at the best but slow. To erode the valleys to so great a depth beneath the level of the upper alluvia, must have demanded a period of many centuries. There can therefore be no doubt of the high antiquity of these deposits. They have yielded the remains of many mammals, some of them extinct, together with the flint flakes made by man. From the nature and structure of some of the high-lying gravels, there can be little doubt that they were formed at a time when the rivers were larger than now, and were liable to be frozen and to be obstructed by large accumulations of ice. We are thus able to connect the formations of the human period with some of the later phases of the Ice Age in the west of Europe.

From the evidence of caverns and river-alluvia of Britain, Germany, and France, Dawkins enumerates about fifty mammals as among the chief inhabitants of Europe during the early human period. They include many of the animals still found wild in Europe, Asia, or Africa, such as the marmot, hare, beaver, lemming, leopard, lynx, wild cat, otter, brown bear, wolf, fox, African elephant, musk sheep, chamois, wild boar, horse, reindeer, and hippopotamus. It will be observed what a remarkable mixture there is in this list of forms now found in alpine or arctic regions, on the one hand, with others only now to be seen in warm latitudes. Probably these continued to be great alternations of climate and changes in the distribution of food, so that migrations successively from opposite quarters took place into central and western Europe. But among the denizens of these regions were some that have been long extinct, such as the mammoth, *Elephas antiquus*, *Melchiorodus latidens*, the woolly rhinoceros, the Irish elk, and others. That man was the contemporary of these extinct forms is shown both by the association of his flint weapons with their remains, and by the discovery of a track of this mammoth with an admirable outline of the animal carved upon it. This valuable relic, with bones of the reindeer and stag admirably sculptured into likenesses of these animals, was found in one of the caves of Pongord in central France.

From the beds of lakes, and from peat-mosses, evidences of more advanced civilization have been obtained. In Switzerland and elsewhere, remains of wooden pile-dwellings have been observed during times when the water has been low. Associated with these are weapons and implements of stone, in other cases of bronze and of iron, pottery, rude kinds of cloth, seeds of different cereals, and bones of domesticated animals. The dog, swine, goat, horned sheep, and other familiar animals appear as the companions of man. But there is evidence that some of the creatures which he tamed to his use were not natives of Europe, but had their original stocks in central Asia, and that some of his grains must likewise have been introduced. Hence we have glimpses into some of the early human migrations from that eastern centre whence so many successive waves of population have invaded Europe.

The later chronicles of the geologist merge insensibly into those of the archaeologist. The latter claims as his field whatever belongs to the history of man on the globe; the former includes the history of man in that larger history of the earth of which a brief outline has been given in the foregoing pages.

POST-TERTIARY SERIES IN NORTH AMERICA.

The general succession of events in post-Tertiary times appears to have been nearly the same over the northern hemisphere both in the New and the Old World. In North America we have the same sharply-defined line between the older post-Tertiary deposits and previous formations, due to the glacial conditions which, overspreading these regions, in great measure destroyed the superficial accumulations of the immediately preceding eras. The Quaternary or post-Tertiary formations are grouped by American geologists in the following subdivisions:—

4. Recent and Post, alluvium, blown sand, "alkali" deposits, Prohistoric, geyser deposits, cave deposits, artificial mounds.
3. Tertiary, River-terraces, loess.
2. Champlain, Raised beaches.
1. Champlain, River-terraces, Champlain clays, *Leda* clay.

1. *Glacial*.—As in Europe, the glacial deposits increase in thickness and variety from south to north. The southern limit of the unstratified drift lies somewhere in the neighborhood of the 39th parallel of north latitude, and the deposit ranges from the Atlantic westward to the meridian of 98°. It spreads, therefore, across British North America, and is found over a considerable area of the north-eastern States. It rises to a height of 5800 feet among

the White Mountains. The absence of any true boulder-drift on the Rocky Mountain slope, where it might have been looked for, is remarkable.

Underneath the boulder-clay the solid rocks, as in Europe, are often well stratified. The direction of the strata is generally southward, varying to south-east and south-west according to the form of the ground. In recent years extensive ice-worn rock-surfaces have been observed among the Rocky Mountains by Hayden, King, and others, proving that these elevations formerly possessed their glaciers, if they were not buried under the great ice-sheet.

The drift bears evidence to a general southward transport of material, and, in conjunction with the striated rocks, shows that the great ice-sheet moved from north to south at least as far as about the latitude of Washington. Logan mentions that in some parts of Canada the glacial drift and boulders run in ridges north and south, thus corresponding with the general direction of transport, like the "drums" in Britain. As in Europe, the coarse boulder-clay at the base of the Quaternary deposits is essentially unfossiliferous.

2 *Champlain*.—Under this name American geologists class the sands, gravels, and clays which evolve the lower boulder-drift. These deposits include coarse unstratified gravels, as well as finely-stratified clays. In eastern Canada they are well developed, and show the following subdivisions:—

- | | |
|---------|--|
| Upper { | St Maurice and Soiel sands, <i>Sarcelia</i> sand of Montreal, upper sand and gravel of Beaufort, upper Champlain clay and sand of Vermont. |
| Lower { | Leda clay of the St Lawrence and Ottawa, lower shell-sand of Beaufort, lower Champlain clay of Vermont. |

The lower subdivisions consist chiefly of clays, which rise to a height of 600 feet above the sea. They have some unstratified beds of siliceous sand, but few boulders. They contain marine organisms, such as *Leda tenacata*, *Sarcelia rugosa*, *Tellina Owenioides*, bones of seals, whales, &c. On the banks of the Ottawa, in Gloucester, the clays contain numerous nodules which have been found round organic bodies, particularly the fish *Molluscos villosus* or capelin of the Lower St Lawrence. Dawson also obtained numerous remains of terrestrial marsh plants, grasses, canes, mosses, and algae. This writer states that about 100 species of marine invertebrates have been obtained from the clays of the St Lawrence valley. All except one or five species in the older part of the deposits are shells of the bivalve or Astarte regions of the Atlantic, and about half are found also in the glacial clays of Britain. The great majority are now living in the Gulf of St. Lawrence and neighbouring coasts, especially off Labrador.¹

3 *Tenacae*.—This division includes the tenacal deposits of alluvial material so marked along the river valleys and lake margins in the northern part of the United States and in Canada, and found also in some degree along the sea-coast. These deposits occur in successive platforms or terraces, marking the contraction in volume of the lakes and rivers, consequently, probably, upon intermittent upheavals of the land. They are well developed round the great lakes. Thus in the basin of Lake Huron deposits of fine sand and clay containing fresh-water shells rise to a height of 40 feet or more above the present level of the water, and run back from the shore sometimes for 20 miles. Regular terraces, corresponding to former water-levels of the lake, run for miles along the shores at heights of 120, 150, and 200 feet. Shingle beaches and mounds or ridges, exactly like those now in course of formation along the exposed shores of Lake Hmon, can be recognized at heights of 60, 70, and 100 feet. Unfossiliferous terraces occur abundantly on the margin of Lake Superior. At one point mentioned by Logan, no fewer than seven of these ancient beaches occur at intervals up to a height of 331 feet above the present level of the lake.² Most of the rivers are bordered with lines of terraces, as in the well-known example of the Connecticut valley described by Hitchcock. The rivers are believed to have had their maximum volume at the beginning of the Tertiary epoch, swollen doubtless by the melting of the still existing ice-sheets and snow-fields. Their work consisted partly in depositing fine alluvium or loess over their flood-plains, partly in scouring their channels out of the Champlain formations. Greater elevation towards the interior, by augmenting their slope, increased their excavating power.

Terraces of marine origin likewise occur both on the coast and far inland. On the coast of Maine they occur at heights of 150 to 200 feet, round Lake Champlain at least as high as 300 feet, and at Montreal nearly 500 feet above the present level of the sea. In the absence of organic remains, however, it is not always possible to distinguish between terraces of marine origin marking former sea-margins, and those left by the retirement of rivers and lakes. In the Bay of Fundy evidence has been cited by Dawson to prove subsidence, for he has observed there a submerged forest of pine and beech lying 25 feet below high-water mark.³

⁴ *Recent and Prehistoric*.—The deposits in this group are essen-

² *Aquilian Geology*, p. 23.

³ *Geology of Canada*, p. 910.

tially the same with those in Europe, and, as in that continent so in America, no definite lines can be drawn within which they should be confined. They cannot be sharply separated from the Tertiary series, on the one hand, nor from modern accumulations, on the other. Besides the marshes, peat-bogs, and other organic deposits which belong to an early period in the human occupation of America, some of the younger alluvia of the river-valleys and lakes can be dated with a high antiquity, though they have not supplied the same copious evidence of early man which gives so much interest to the corresponding European formations. Heaps of shells of edible species occur on the coasts of Nova Scotia, Maine, &c. The large mounds of artificial origin in the Mississippi valley have excited much attention.

PART VII.—PHYSIOGRAPHICAL GEOLOGY.

In the investigation of the geological history of any country, two questions present themselves. We have first to consider the nature and arrangement of the rocks which underlie the surface, and to ascertain from them what has been the march of events, what changes in geography have successively taken place, and what races of plants and animals have come and gone. The gradual geological evolution of the earth has been sketched in the foregoing part of this article. But besides the history of the solid rocks beneath the surface of the land, there is that of the surface itself. Mountains and plains, valleys and ravines, cliffs, peaks, passes, lakes, and the many other features of a country demand attention. By what processes have these varied outlines been impressed upon the surface of the globe? Are they of different ages, and if so, how can their history be ascertained?

The branch of geological inquiry which endeavours to answer these questions has been termed Physiography or Physio-graphical Geology. Its investigations evidently demand an acquaintance with Stratigraphical Geology. We must be able to trace out the former geographical conditions of the globe before we can adequately reason on the origin of those now existing. Hence the consideration of this branch of the subject has necessarily been reserved for this concluding section.

The stratified formations, of which the succession and history have been traced in the previous pages, were chiefly laid down on the sea-floor in wide horizontal or gently inclined sheets. They have since been upraised into land, their horizontality has been in great part destroyed; and they have been enormously wasted by denuding agents. In considering therefore how they have acquired their present external forms, we have to deal with the effects of two kinds of forces, one acting from below, the other on the surface. These stratified rocks were, on the whole, deposited in shallow water, and have been repeatedly upraised and denuded, so that the younger have been formed out of the waste of the older. They have their modern counterparts, not in the deposits of the great ocean-basins, but in those of comparatively shallow seas. The inference to be drawn from these facts is that the present continental regions, through many local oscillations, have existed as terrestrial ridges from a remote geological antiquity, and that the ocean basins in like manner have, on the whole, retained their identity. When the geologist asks himself how the present distribution of sea and land is to be accounted for, he finds that the answer to the question goes back to early Palaeozoic times, whence he can in some cases trace the gradual growth of a continent downward through the long cycles of geological time. But there still remains the problem to account for the original wrinkling of the surface of the globe, whereby the present great ridges and hollows were produced.

It is now generally agreed that these inequalities have been produced by unequal contraction of the earth's mass, the interior contracting more than the outer crust, which must therefore have accommodated itself to this diminution of diameter by undergoing corrugation. But there seems

to have been some original distribution of materials in the globe that initiated the depressions on the areas which they have retained. It has been already pointed out (*ante*, p. 223) that the matter underlying the oceans is more dense than that beneath the continents, and that, partly at least, to this cause must the present position of the oceans be attributed. The early and persistent subsidence of these areas, with the consequent increase of density, seems to have determined the main contours of the earth's surface.

From what has been stated in part iv., the reader will understand that rocks which were originally horizontal, or nearly so, have been crumpled over tracts thousands of square miles in extent, so as to occupy now a superficial area greatly less than that which they originally covered. It is evident that they have been horizontally compressed, and that this result can only have been achieved as a consequence of the subsidence of such a curved surface as that of our globe. The difficulty of explaining these corrugations on the hypothesis of the contraction of a solid globe is undoubtedly great. Mr O. Fisher, indeed, believes that the present inequalities of contour on the earth's surface are from sixty-six to eleven and a half times as great as they would have been had they resulted from the contraction of a solid globe, and he has suggested that the earth need not have become solid throughout simultaneously, and consequently may have been considerably larger than it is now at the time when a solid crust was first formed.¹

The geological phenomena long ago led to a belief in the liquidity of the earth's interior. Since this belief has been so weightily opposed by the physical arguments already adduced (*ante*, p. 225), geologists have endeavoured to modify it in such a way as, if possible, to satisfy the requirements of physics, while at the same time providing an adequate explanation of the corrugation of the earth's crust. Mr Hopkins, Professor Dana, Professor Shaler, and Mr Fisher have, on different grounds, advocated the existence of a fluid or viscous substratum beneath the crust, the contraction and consolidation of which produce the corrugations of the rocks and of the surface. "The increase of temperature," says Mr Fisher, "though rapid near the surface, becomes less and less as we descend, so that, if the earth were once wholly melted, the temperature near the centre is not very greatly above what it is at a depth which, compared to the earth's radius, is small. Consequently, if it requires great pressure to solidify the materials at such a temperature, it is probable that the melting temperature may be reached before the pressure is sufficient to solidify." The crust, of course, must be able to sustain itself on the corrugated surface of the supposed viscous layer without breaking up and sinking. The same writer has even suggested that the observed amount of corrugation is more than can be accounted for even on this hypothesis, and that the shrinkage may have been due not merely to cooling, but to the escape of water from the interior in the form of the superheated steam of volcanic vents.² More recently Herr Siemens has been led, from observations made in May 1878 at Vesuvius, to conclude that vast quantities of hydrogen gas, or combustible compounds of hydrogen, exist in the earth's interior; and that these, rising and exploding in the funnels of volcanoes, give rise to the detonations and clouds of steam.³

Leaving the vexed question of the condition of the earth's interior, the hypothesis of secular cooling and contraction furnishes a natural explanation of the origin of the dominant elevations and depressions of the surface, and of the intense crumpling which the rocks in many regions have undergone. Taking 0.09 as the coefficient of contraction

for a supposed stratum 500 miles thick, lying beneath 25 miles of crust, and passing from a fused into a solid state, Mr Fisher found that every 100 miles measured along a great circle on the surface would have been one mile larger before the contraction, and that this might produce a triangular elevation of "25 square miles on a base of 100 miles, which would give a range of mountains half a mile high. If only 50 miles out of the hundred were disturbed, the range would be a mile high, and so on."⁴

The effects of this lateral pressure may show themselves either in broad dome-like elevations, or in narrower and loftier ridges of mountain. The structure of the crust is so complex, and the resistance offered by it to the pressure is consequently so varied, that abundant cause is furnished for almost any diversity in the forms and distribution of the wrinkles into which it is thrown. It is evident, however, that the folds have tended to follow a linear direction. In North America, from early geological times, they have kept on the whole on the lines of meridians. In the Old World, on the contrary, they have chosen diverse trends, but the last great crumpings—those of the Alps, Caucasus, and the great mountain ranges of central Asia—have risen along parallels of latitude.

Mountain chains must therefore be regarded as evidence of the shrinkage of the earth's mass. They may be the result of one movement, or of a long succession of such movements. Formed on lines of weakness in the crust, they have again and again given relief from the strain of compression by undergoing fresh crumpling and upheaval. The successive stages of uplift are usually not difficult to trace. The chief guide is supplied by unconformability, as explained on p. 318. Let us suppose, for example, that a mountain range consists of upraised Lower Silurian rocks, upon the upturned and denuded edges of which the Carboniferous Limestone lies transgressively. The original upheaval of that range must have taken place at the period of geological time represented by the interval between the Lower Silurian and the Carboniferous Limestone formations. If, in following the range along its course, we found at last the Carboniferous Limestone also highly inclined and covered unconformably by the Upper Coal-measures, we should know that a second uplift of that portion of the ground had taken place between the time of the Limestone and that of the Upper Coal-measures. By this simple and obvious kind of evidence the relative ages of different mountain chains may be compared. In most great mountain-chains, however, the rocks have been so intensely crumpled, and even inverted, that much labour may be required before their true relations can be determined.

The Alps offer an instructive example of a great mountain chain formed by repeated movements during a long succession of geological periods. As has been already stated, the central portions of the chain consist of gneiss, schists, granite, and other crystalline rocks, partly referable to the Archaean series, but many of which appear to be metamorphosed formations of Palaeozoic, Secondary, and even of older Tertiary age.

It would appear therefore that the first outlines of the Alps were traced out even in Archaean times, and that after submergence, and the deposit of Palaeozoic formations along their flanks, if not over most of their site, they were re-elevated into land. From the relations of the Mesozoic rocks to each other, we may infer that several renewed uplifts after successive denudations took place before the beginning of the Tertiary formations. A large part of the range was, as we have seen, submerged during the Eocene period under the waters of that wide sea which spread across the centre of the Old World, and in which the Nummulitic Limestone and Pliach were deposited. But about the close of that period the grand upheaval took place to which the present magnitude of the mountains is chiefly due. The older Tertiary rocks, previously horizontal under the sea, were raised up into land, crumpled, dislocated, inverted, together with all the older formations of the chain. So intense was the compression to which the Eocene clays and sands were subjected

¹ *Cambridge Phil. Trans.*, vol. xii. pt. ii., 1875.

³ *Monatsbericht der K. preuss. Akad. Wissenschaft.*, 1878 p. 558.

⁴ *Cambridge Phil. Trans.*, vol. xi. pt. iii.

that they were converted into rocks as hard and crystalline as many of the Paleozoic masses. It is strange to reflect that the enduring materials out of which so many of the mountains, cliffs, and pinnacles of the Alps have been formed are of no higher geological antiquity than the London Clay and other soft Eocene deposits of the south of England. After the paroxysm of elevation had ended, one or more large lakes were formed along the northern base of the mountains. In these hollows the Swiss molasse accumulated to a depth of more than 6000 feet—a great pile of slowly formed gravels, sands, and clays. That the sea gained occasional access to the region is shown by the intercalation of bands containing marine organisms, as already stated (*ante*, p. 363). Not improbably a gradual subsidence of the region was going on during the formation of the molasse. But towards the close of the Miocene period another great epoch of mountain-making was ushered in. The lakes disappeared, and their thick sediments were thrust up into large, broken, mountain masses. The Rigi, Rossberg, and other prominent heights along the northern flank of the Alps are formed of these upheaved lacustrine deposits. Since that great movement no paroxysm seems to have affected the Alpine region. Ceaseless changes, indeed, have been in progress, but they have been due not so much to subterranean causes as to those subaerial forces which are still so active.

The gradual evolution of a continent during a long succession of geological periods has been admirably worked out for North America by Dana, King, Hayden, Newberry, Powell, Dawson, and others. The general character of the structure is extremely simplicity, as compared with that of the Old World. In the Rocky Mountain region, for example, while the Paleozoic formations lie unconformably upon the Archean gneiss, there is, according to King, a regular conformable sequence from the Lower Silurian to the Jurassic rocks. During the enormous interval of time represented by these massive formations what is now the axis of the continent remained undisturbed save by a gentle and protected subsidence. In the great depression thus produced all the Paleozoic and a great part of the Mesozoic rocks were accumulated. At the close of the Jurassic period the first great upheavals took place. Two lofty ranges of mountains,—the Sierra Nevada (now with summits more than 14,000 feet high) and the Wahsatch,—400 miles apart, were pushed up from the great subsiding area. These movements were followed by a prolonged subsidence, during which Cretaceous sediments accumulated over the Rocky Mountain region to a depth of 8000 feet or more. "Then came another vast uplift, whereby the Cretaceous sediments were elevated into the crest of the mountains, and a parallel coast-range was formed fronting the Pacific. Intense metamorphism of the Cretaceous rocks is stated to have taken place. During the Tertiary ages the Rocky Mountains were permanently raised above the sea, and gradually elevated to their present height. Vast lakes existed among them, in which, as in the Miocene basins of the Alps, enormous masses of sediment accumulated. The slopes of the land were clothed with an abundant vegetation, in which, as already stated (*ante*, p. 365), we may trace the ancestors of many of the living trees of North America. One of the most striking features in the later phases of this history was the outpouring of great floods of tephrite and other lavas from many points and fissures over a vast space of the Rocky Mountains. In the Snake River region these lavas have a depth of 700 to 1000 feet, over an area 300 miles in breadth.

These examples show that the elevation of mountains has been occasional and, so to speak, paroxysmal. Long intervals elapsed when a slow subsidence took place, but at last a point was reached when the descending crust, unable any longer to withstand the accumulated lateral pressure, was forced to find relief by rising into mountain ridges. With this effort the elevatory movements ceased. They were followed either by a stationary period, or more usually by a renewal of the gradual depression, until eventually relief was again obtained by upheaval, sometimes along new lines, but often on those which had previously been used.

We see also how, by such enormous compression, the rocks should have acquired a cleavage structure (*ante*, p. 302). Soft clays have been squeezed and folded till they have become hard fissile slates. So intense have been the corrugation and compression that the strata have undergone a chemical rearrangement of their particles; they have been "metamorphosed" or changed into schists and gneisses, if indeed some portions of them have not been actually fused and intruded into the surrounding masses as igneous rocks.

The consideration of these changes enables us to realize why the strata of a great mountain chain should rise into

steeper folds as they are traced away from the plains, until they are found at last folded back upon themselves, and the older are made to overlie the younger. Instead of overlying the central and more ancient masses of the range, they seem really to dip into and under them, so that a section across the region might convey the impression of a great syncline instead of a great and complicated anticline. This fan-shaped arrangement of the rocks may be observed even in the single mountains of a great chain. Mount Blanc is a familiar example.

Another piece of geological structure is sometimes brought vividly before us by the examination of these regions of disturbance. Not only have the rocks been crumpled and inverted, they have likewise been traversed by great dislocations. Those on one side of a fissure have been pushed bodily over those on the other side, or they have experienced a vertical displacement of hundreds or even thousands of feet. As a rule, however, dislocations are more easily traced, if they are not also larger and more numerous, among the low grounds than among the mountains. One of the most remarkable and important faults in Europe is that which bounds the southern edge of the Belgian coal-field. It can be traced across Belgium, has recently been detected in the Boulonnais (*ante*, p. 350, *note*), and may not improbably run beneath the Secondary and Tertiary rocks of the south of England. It is a remarkable fact that faults which have a vertical displacement of many thousands of feet produce little or no effect upon the surface. The great Belgian fault, for example, is crossed by the valleys of the Meuse, and other northerly-flowing streams. Yet so indistinctly is it marked in the Meuse valley that no one would suspect its existence from any peculiarity in the general form of the ground, and even an experienced geologist, until he had learned the structure of the district, would scarcely detect any fault at all.

With the fractures along mountain chains we may connect the hot springs so frequently to be met with in these regions. But the most important connexion with the heated interior is that established by volcanic vents. The theory of secular contraction, while affording a rational explanation of the origin of the great terrestrial ridges, serves at the same time to show why volcanoes should so frequently rise along these ridges (*ante*, p. 254). The elevation of the crust, by diminishing the pressure on the parts beneath the upheaved tracts, permits them to assume a liquid condition, and to rise within reach of the surface when, driven upward by the expansion of superheated vapours, they are ejected in the form of lava or ashes.

It appears therefore that the present contours of the earth's surface must be due in large measure to the effects of the contraction of a cooling globe. The crust has been repeatedly corrugated, sometimes suffering sudden and paroxysmal shocks, at other times undergoing slow and long-continued upheaval and depression.

But these subterranean movements form only one phase of the operations by which the outlines of the land have been produced. They have ridged up the solid crust above the sea-level, and have thus given rise to land, but the land as we now see it has acquired its features from the prolonged and varied action of the epigene agencies upon rocks of very varied heights and powers of resistance.

It is evident that, as a whole, the land suffers ceaseless erosion from the time that it appears above water. It is likewise clear, from the nature of the materials composing most of the rocks of the land, that they have been derived from old denudations of the same kind. And thus, side by side with the various upheavals and subsidences, there has been a continuous removal of materials from the land, and an equally persistent deposit of these materials under water, and consequent growth of new rocks.

This degradation of the surface may be apply compared to a process of sculpturing, which begins as soon as the land emerges from the sea, and never ceases so long as any portion of the land remains above water. The implements employed by nature in this great work are those epigene forces whose operations have already been described. Each of them, like a special kind of graving tool, produces its own characteristic impress on the land. The work of ice, of frost, of rivers, of glaciers, can be readily discriminated, though they all combine harmoniously towards the achievement of their one common task. Hence the present contours of the land must depend partly (1) on the vigour with which the several epigene agents perform their work of erosion, (2) on the original configuration of the ground, and the influence it may have had in guiding the operations of these agents, and (3) on the varying structure and powers of resistance possessed by the rocks.

1. Taking a broad view of denudation, we may conveniently group together the action of air, frost, springs, rivers, glaciers, and the other agents which wear down the surface of the land, under the one common designation of subaerial, and that of the sea as marine. The general results of subaerial action are—to furrow and channel the land, to erode valleys, to sharpen and splinter the ridges of mountains, and thus, while roughening, to lower the general surface and carry out the detritus to the sea. The action of the sea, on the other hand, is to plane down the land to the level at which the influence of breakers and ground-swell ceases to have any erosive effect; the flat platform, so often visible between tide-marks on a rocky exposed coast-line, is an impressive illustration of the tendency of marine denudation. The combined result of subaerial and marine action, if unimpeded by any subterranean movement, would evidently be to reduce the land to one general level under the sea. For, except in that upper marginal zone where the waves and tidal currents play, the waters of the ocean protect the solid rocks which they cover. And the rocks indeed can find no permanent protection anywhere else. But to reduce a large area of land such as a continent to the condition of a submarine plain, would require a longer period of time than seems to have elapsed between two epochs of upheaval. Traces of ancient plains of marine denudation are to be met with in Scandinavia and in Scotland, on but a comparatively small scale, as if there had been time for only a narrow platform to be formed before the next paroxysm of contraction and uplift completely renovated the geography of the region.

Instead of trying to estimate how much work is done by each of the subaerial agents in eroding the land, we gain a much more impressive idea of the reality and magnitude of their work as a whole by treating their operations as one great process, the effects of which can be actually measured. The true gauge of the present yearly waste of the surface of the land is furnished by the amount of mineral matter carried every year into the sea by rivers. This mineral matter is partly in mechanical suspension, partly in chemical solution, and is to no small extent pushed in the form of shingle and sand along the bottoms of the streams. Some data respecting its amount have been already given (*ante*, pp 274, 278). If we take the ratios furnished by the Mississippi as a fair average, which, from the vast area and varied climatal and geographical characters of the region drained by that river, they probably are, then we learn that $\frac{1}{1000}$ th of a foot is worn away from the general surface of the land every year. At this rate, if the present erosion could be sustained, the whole American continent, of which, according to Humboldt, the mean height is 748 feet, would be worn down to the sea-level in about $4\frac{1}{2}$ millions of years—a comparatively short period in geological chronology. It is obvious, however, that the denudation is not equally

distributed over the whole surface of the land. If $\frac{1}{1000}$ th of a foot is the mean rate from the whole surface, then some parts, including the more level grounds, must lose very much less than that amount, while other parts, such as the slopes and valleys, must lose very much more. The proportions between these extremes must continually vary throughout every country, according to angle of declivity, nature of surface, amount and distribution of rainfall, and whether the rain is spread over the year or concentrated into a short period.

The proportion between the area covered by the more level ground of a country, where the rate of denudation is least, and that of the declivities, valleys, and stream channels, where that rate is greatest, may be assumed as nine to one. The extent of the annual waste may be further taken to be nine times greater over the latter than over the former, so that, while the more level parts of the surface have been lowered 1 foot, the valleys have lost 9 feet. Taking the mean rates of waste over the whole area to be $\frac{1}{1000}$ th of a foot per annum we find that on these data the annual loss amounts to $\frac{1}{100}$ ths of a foot from the flatter grounds and 5 feet from the valleys in 6000 years. This is equal to a loss of 1 foot from the former in 10,800 years and from the later in 1200 years, or to $\frac{1}{10}$ th of an inch from the one in 75 and from the other in 8½ years. At this rate of erosion, a valley 1000 feet deep may be excavated in 1,200,000 years. These estimates are only approximations to the truth, but they are valuable in directing attention to the real efficacy of the apparently insignificant subaerial denudation now in progress. Any other estimates of the relative amount of material worn away from the different parts of the surface may be taken, but the mean annual loss from the whole area, as ascertained by the river discharge, remains unaffected. If we represent too large an amount as removed from the valleys we diminish the loss from the open country, or if we make the contingent derived from the latter too great we lessen that from the former.

2. From this reasoning it follows that, apart altogether from irregularities of surface due to inequalities of upheaval, every area of land exposed to ordinary subaerial action must, in the end, be channelled into a system of valleys. Even a smooth featureless tract elevated uniformly above the sea would eventually be widely and deeply eroded. Nor would this require a long geological period, for, at the present rate of waste in the Mississippi basin, valleys 800 feet might be carved out in a million years. Undoubtedly the original features superinduced by subterranean action would guide and modify the operations of running water, though their influence would certainly wane as the features themselves slowly disappeared. In no case probably would the aboriginal contour remain through a succession of geological periods. Traces of it might still be discernible, but they would be well-nigh effaced by the new outlines produced by the superficial agents. In the vast tablelands of Colorado and the other western territories of the United States an impressive picture is visible of the results of mere subaerial erosion on undisturbed and nearly level strata. Systems of stream-courses and valleys, river gorges unexampled elsewhere in the world for depth and length, vast winding lines of escarpment, like runges of sea-cliffs, terraced slopes rising from plateau to plateau, huge buttresses and solitary stacks standing like islands out of the plains, great mountain masses towering into picturesque peaks and pinnacles cleft by innumerable gullies, yet everywhere marked by the parallel bars of the horizontal strata out of which they have been carved—these are the orderly symmetrical characteristics of a country where the scenery is due entirely to the action of subaerial agents on the one hand and the varying resistance of perfectly regular stratified rocks on the other. The Alps, on the contrary, present an

instructive example of the kind of scenery that arises where a mass of high ground has resulted from the intense corrugation and upheaval of a complicated series of stratified and crystalline rocks, subsequently for a vast period carved by rain, frost, springs, and glaciers. We see how, on the outer flanks of those mountains among the ridges of the Jura, the strata begin to undulate in long wave-like ridges, and how, as we enter the main chain, the undulations assume a more gigantic tumultuous character, until, along the central heights, the mountains lift themselves towards the sky like the storm-swept crests of vast earth billows. The whole aspect of the ground suggests intense commotion. Where the strata appear along the cliffs or slopes they may often be seen twisted and crumpled on the most gigantic scale. Out of this complicated mass of material the subaerial forces have been ceaselessly at work since its first elevation. They have cut out valleys, sometimes along the original depressions, sometimes down the slopes. They have eroded lake-basins, dug out cornices or *cirques*, notched and furrowed the ridges, splintered the crests, and have left no part of the original surface unmodified. But they have not effaced all traces of the convulsions by which the Alps were upheaved.

3. The details of the sculpture of the land have mainly depended on the nature of the materials on which nature's erosive tools have been employed. The joints by which all rocks are traversed have served as dominant lines along which the rain has filtered, and the springs have risen, and the frost wedges have been driven. On the high bare scarps of a high mountain the inner structure of the mass is laid open, and there the system of joints is seen to have determined the lines of crest, the vertical walls of cliff and precipice, the forms of buttress and recess, the position of cleft and chasm, the outline of spire and pinnacle. On the lower slopes, even under the tapestry of verdure which nature delights to hang where she can over her naked rocks, we may detect the same pervading influence of the joints upon the forms assumed by ravines and crags. Each kind of rock, too, gives rise to its own characteristic form of scenery. The massive crystalline rocks, such as granite, yield each in its own fashion to the resistless attacks of the denuding forces. They are broadly marked off from the stratified rocks in which the parallel bands of the bedding form a leading feature in every cliff and bare mountain slope. Among the latter rocks also very distinctive types of surface may be observed. A range of sandstone hills, for example, presents a marked contrast to one of limestone.

In the physiography of any region, the mountains are the dominant features. A true mountain chain consists of rocks which have been crumpled and pushed up in the manner already described. But ranges of hills almost mountainous in their bulk may be formed by the gradual erosion of valleys out of a mass of original high ground. In this way some ancient tablelands, those of Norway and of the Highlands of Scotland, for example, have been so channelled by deep fjords and glens that they now consist of massive rugged hills, either isolated or connected along the flanks. The forms of the valleys thus eroded have been governed partly by the structure and composition of the rocks, and partly by the relative potency of the different denuding agents. Where the influence of rain and frost has been slight, and the streams, supplied from distant sources, have had sufficient declivity, deep, narrow, precipitous ravines or gorges have been excavated. The cañons of the Colorado are a magnificent example of this result. Where, on the other hand, ordinary atmospheric action has been more rapid, the sides of the river channels have been attacked, and open sloping glens and valleys have been hollowed out. A gorge or defile is usually due to the action of a waterfall, which, beginning with some abrupt declivity or

precipice in the course of the river when it first commenced to flow, or caused by some hard rock crossing the channel, has eaten its way backward, as already explained (p. 276).

Lakes may have been formed in several ways. 1. By subterranean movements as, for example, during those which gave rise to mountain chains. But these hollows, unless continually deepened by subsequent movements of a similar nature would be filled up by the sediment continually washed into them from the adjoining slopes. The numerous lakes in such a mountain system as the Alps cannot be due merely to this cause, unless we suppose the upheaval of the mountains to have been geologically quite recent, or that subsidence must take place continuously or periodically below each independent basin. But there is evidence that the upheaval of the lakes is not of recent date, while the idea of perpetuating lakes by continual subsidence would demand, not in the Alps merely, but all over the northern hemisphere where lakes are so abundant, an amount of subterranean movement of which, if it really existed, there would assuredly be plenty of other evidence. 2. By irregularities in the deposition of superficial accumulations prior to the elevation of the land or during the disappearance of the ice-sheet. The numerous tarns and lakes enclosed within mounds and ridges of drift-clay and gravel are examples. 3. By the accumulation of a barrier across the channel of a stream and the consequent ponding back of the water. This may be done, for instance, by a landslide, by the advance of a glacier across a valley, or by the throwing up of a bank by the sea across the mouth of a river. 4. By erosion. The only agent capable of excavating hollows out of the solid rock such as might form lake-basins is glacier-ice (*ante*, p. 282). It is a remarkable fact, of which the significance may now be seen, that the innumerable lake-basins of the northern hemisphere lie on surfaces of intensely ice-worn rock. The striae can be seen on the smoother rock-surfaces slipping into the water on all sides. These striae were produced by ice moving over the rock. If the ice could, as the striae prove, descend into the rock-basins and mount up the farther side, smoothing and striating the rock as it went, it could erode the basins. It is hardly possible to convey in words an adequate conception of the enormous extent to which the north of Europe and North America has had its surface ground down by ice. The ordinary rough surfaces produced by atmospheric disintegration have been replaced by a peculiar flowing contour which is traceable even to below the sea-level.

In the general subaerial denudation of a country, innumerable minor features are worked out as the structure of the rocks controls the operations of the eroding agents. Thus, among comparatively undisturbed strata, a hard bed resting upon others of a softer kind is apt to form along its outcrop a line of cliff or escarpment. Though a long range of such cliffs resembles a coast that has been worn by the sea, it may be entirely due to more atmospheric waste. Again, the more resisting portions of a rock may be seen projecting as crags or knolls. An igneous mass will stand out as a bold hill from amidst the more decomposable strata through which it has risen. These features, often so marked on the lower grounds, attain their most conspicuous development among the higher and barer parts of the mountains, where subaerial disintegration is most rapid. The torrents tear out deep gullies from the sides of the declivities. Corries are scooped out on the one hand, and naked precipices are left on the other. The harder bands of rock project as massive ribs down the slopes, shoot up into prominent *aiguilles*, or give to the summits the notched saw-like outlines they so often present.

Tablelands may sometimes arise from the abrasion of hard rocks and the production of a level plain by the action of the sea, or rather of that action combined with the previous

degradation of the land by subaerial waste. But most of the great tablelands of the globe seem to be platforms of little-disturbed strata which have been upraised bodily to a considerable elevation. No sooner, however, are they placed in that position than they are attacked by running water, and begin to be hollowed out into systems of valleys. As the valleys sink, the platforms between them grow into narrower and more definite ridges, until eventually the level tableland is converted into a complicated network of hills and valleys, wherein, nevertheless, the key to the whole arrangement is furnished by a knowledge of the disposition and effects of the flow of water. The examples of this process brought to light in Colorado, Wyoming, Nevada, and the other western territories, by Newberry, King, Hayden, Powell, and other explorers, are among the most striking monuments of geological operations in the world.

The materials worn from the surface of the higher are spread out over the lower grounds. We have already traced how streams at once begin to drop their freight of sediment

when, by the lessening of their declivity, their carrying power is diminished (p. 276-7). The great plains of the earth's surface are due to this deposit of gravel, sand, and loam. They are thus monuments at once of the destructive and reproductive processes which have been in progress unceasingly since the first land rose above the sea and the first shower of rain fell. Every pebble and particle of their soil, once part of the distant mountains, has travelled slowly and fitfully downward. Again and again have these materials been shifted, ever moving downward and sea-ward. For centuries, perhaps, they have taken their share in the fertility of the plains and have ministered to the necessities of flower and tree, of the bird of the air, the beast of the field, and of man himself. But their destiny is still the great ocean. In that bourn alone can they find undisturbed repose, and there, slowly accumulating in massive beds, they will remain until, in the course of ages, renewed upheaval shall raise them into future land, there once more to pass through the same cycle of change.

G E O M E T R Y

PART I.—PURE GEOMETRY.

GEOMETRY has been divided since the time of Euclid into an "elementary" and a "higher" part. The contents and limits of the former have been fixed by Euclid's *Elements*. The latter included at the time of the Greek mathematicians principally the properties of the conic sections and of a few other curves. The methods used in both were essentially the same. These began to be replaced during the 17th century by more powerful methods, invented by Roberval, Pascal, Desargues, and others. But the impetus which higher geometry received in their works was soon arrested, in consequence of the discoveries of Descartes,—the new calculus to which these gave rise absorbing the attention of mathematicians almost exclusively, until Monge, at the end of the 18th century, re-established "pure" as distinguished from Descartes's "coordinate" (or analytical) geometry. Since then the purely geometrical methods have been continuously extended, especially by Poncelet, Steiner, Von Staudt, and Cramona, and in England by Hirst and Henry Smith, to mention only a few of the leading names.

Whilst higher geometry thus made most rapid progress, the elementary part remained almost unaltered. It has been taught up to the present day on the basis of Euclid's *Elements*, the latter being either used directly as a textbook (in England), or being replaced (in most parts of the Continent) by text-books which are essentially Euclid's *Elements* rewritten, with a few additions about the mensuration of the circle, cone, cylinder, and sphere. Only within a very recent period have attempts been made to change the character of the elementary part by introducing some of the modern methods.

We shall give in this article—first, a survey of elementary geometry as contained in Euclid's *Elements*, and then, in form of an independent treatise, an introduction to higher geometry, based on modern methods. In the former part we shall suppose that a copy of Euclid's *Elements* is in the hands of the reader, so that we may dispense, as a rule, with giving proofs or drawing figures. We thus shall give only the contents of his propositions grouped together in such a way as to show their connexion, and often expressed in words which differ from the verbal translation in order to make their meaning clear. It will make little difference which of the many English editions of Euclid's *Elements* the reader takes. Of these we may mention Simson's, Potts's, and Todhunter's.

SECTION I.—ELEMENTARY OR EUCLIDIAN GEOMETRY.

The Axioms.

§ 1. The object of geometry is to investigate the properties of space. The first step must consist in establishing those fundamental properties from which all others follow by processes of deductive reasoning. They are laid down in the Axioms, and these ought to form such a system that nothing need be added to them in order fully to characterize space, and that nothing may be left out without making the system incomplete. They must, in fact, completely "define" space. Several such systems are conceivable. Euclid has given one, others have been put forward in recent times by Riemann (*Abhandl. der königl. Gesellschaft zu Göttingen*, vol. xiii.) by Helmholtz (*Göttinger Nachrichten*, June 1868), and by Grassmann (*Ausdehnungslehre* vom 1844). How many axioms the system ought to contain, and which system is the simplest, may be said to be

still an open question. We shall consider only Euclid's system.

§ 2. The axioms are obtained from inspection of space and of solids in space,—hence from experience. The same source gives us the notions of the geometrical entities to which the axioms relate, viz, solids, surfaces, lines or curves, and points. A solid is directly given by experience; we have only to abstract all material from it in order to gain the notion of a geometrical solid. This has shape, size, position, and may be moved. Its boundary or boundaries are called surfaces. They separate one part of space from another, and are said to have no thickness. Their boundaries are curves or lines, and these have length only. Their boundaries, again, are points, which have no magnitude but only position. We thus come in three steps from solids to points which have no magnitude; in each step we lose one extension. Hence we say a solid has three dimensions, a surface two, a line one, and a point none. Space itself, of which a solid forms only a part, is also said to be of three dimensions. The same thing is intended to be expressed by saying that a solid has length, breadth, and thickness, a surface length and breadth, a line length only, and a point no extension whatsoever.

Euclid gives the essence of these statements as definitions.—

Def 1, I. *A point is that which has no parts, or which has no magnitude.*

Def 2, I. *A line is length without breadth.*

Def 5, I. *A superficies is that which has only length and breadth.*

Def 1, XI. *A solid is that which has length, breadth, and thickness.*

If we allow motion in geometry,—and it seems impossible to avoid it,—we may generate these entities by moving a point, a line, or a surface, thus:—

The path of a moving point is a line.

The path of a moving line is, in general, a surface.

The path of a moving surface is, in general, a solid.

And we may then assume that the lines, surfaces, and solids, as defined before, can all be generated in this manner. From this generation of the entities it follows again that the boundaries—the first and last position of the moving element—of a line are points, and so on; and thus we come back to the considerations with which we started.

Euclid points this out in his definitions,—Def. 3, I., Def. 6, I., and Def. 2, XI. He does not, however, show the connexion which these definitions have with those mentioned before. When points and lines have been defined, a statement like Def. 3, I., "The extremities of a line are points," is a proposition which either has to be proved, and then it is a theorem, or which has to be taken for granted, in which case it is an axiom. And so with Def. 6, I., and Def. 2, XI.

§ 3. Euclid's definitions mentioned above are attempts to describe, in a few words, notions which we have obtained by inspection of and abstraction from solids. A few more notions have to be added to these, principally those of the simplest line—the straight line, and of the simplest surface—the flat surface or plane. These notions we possess, but to define them accurately is difficult. Euclid's Definition 4, I., "A straight line is that which lies evenly between its extreme points," must be meaningless to any one who has not the notion of straightness in his mind. Neither does it state a property of the straight line which can be used in any further investigation. Such a property is given in Axiom 10, I. It is really this axiom, together

with Postulates 2 and 3, which characterizes the straight line.

Whilst for the straight line the verbal definition and axiom are kept apart, Euclid mixes them up in the case of the plane. Here the Definition 7, I., includes an axiom. It defines a plane as a surface which has the property that every straight line which joins any two points in it lies altogether in the surface. But if we take a straight line and a point in such a surface, and draw all straight lines which join the latter to all points in the first line, the surface will be fully determined. This construction is therefore sufficient as a definition. That every other straight line which joins any two points in this surface lies altogether in it is a further property, and to assume it gives another axiom.

Thus a number of Euclid's axioms are hidden among his first definitions. A still greater confusion exists in the present editions of Euclid between the postulates and axioms so-called, but this is due to later editors and not to Euclid himself. The latter had the last three axioms put together with the postulates (*ἀξιώματα*), so that these were meant to include all assumptions relating to space. The remaining assumptions which relate to magnitudes in general, viz., the first eight "axioms" in modern editions, were called "common notions" (*κοινὰ ἔννοιαι*). Of the latter a few may be said to be definitions. Thus the eighth might be taken as a definition of "equal," and the seventh of halves. If we wish to collect the axioms used in Euclid's *Elements*, we have therefore to take the three postulates, the last three axioms as generally given, a few axioms hidden in the definitions, and an axiom used by Euclid in the proof of Prop. 4 and on a few other occasions, viz., that figures may be moved in space without change of shape or size.

We shall not enter into the investigation how far the assumptions which would be included in such a list are sufficient, and how far they are necessary. It may be sufficient here to state that from the beginning of a geometrical science to the present century attempts without end have been made to prove the last of Euclid's axioms, that only at the beginning of the present century the futility of this attempt was shown, and that only within the last twenty years the true nature of the connexion between the axioms has become known through the researches of Riemann and Helmholtz, although Grassmann had published already, in 1844, his classical but long-neglected *Ausdehnungslehre*.

§ 4. The assumptions actually made by Euclid may be stated as follows:—

1. Straight lines exist which have the property that any one of them may be produced both ways without limit, that through any two points in space such a line may be drawn, and that any two of them coincide throughout their indefinite extensions as soon as two points in the one coincide with two points in the other (These gives the contents of Def. 4, part of Def. 35, the first two Postulates, and Axiom 10.)

2. Plane surfaces or planes exist having the property laid down in Def. 7, that every straight line joining any two points in such a surface lies altogether in it.

3. Right angles, as defined in Def. 10, are possible, and all right angles are equal, that is to say, wherever in space we take a plane, and wherever in that plane we construct a right angle, all angles thus constructed will be equal, so that any one of them may be made to coincide with any other. (Axiom 11.)

4. The 12th Axiom of Euclid. This we shall not state now, but only introduce it when we cannot proceed any further without it.

5. Figures may be freely moved in space without change of shape or size. This is assumed by Euclid, but not stated as an axiom.

6. In any plane a circle may be described, having any point in that plane as centre, and its distance from any other point in that plane as radius. (Postulate 3.)

The definitions which have not been mentioned are all "nominal definitions," that is to say, they fix a name for a

thing described. Many of them overdetermine a figure. (Compare notes to definitions in Simson's or Todhunter's edition.)

§ 5. Euclid's *Elements* are contained in thirteen books. Of these the first four and the sixth are devoted to "plane geometry," as the investigation of figures in a plane is generally called. The 5th book contains the theory of proportion which is used in Book VI. The 7th, 8th, and 9th books are purely arithmetical, whilst the 10th contains a most ingenious treatment of geometrical irrational quantities. These four books will be excluded from our survey. The remaining three books relate to figures in space, or, as it is generally called, to "solid geometry." The 7th, 8th, 9th, 10th, 13th, and part of the 11th and 12th books are now generally omitted from the school editions of the *Elements*. In the first four and in the 6th book it is to be understood that all figures are drawn in a plane.

BOOK I. OF EUCLID'S "ELEMENTS."

§ 6. According to the third postulate it is possible to draw in any plane a circle which has its centre at any given point, and its radius equal to the distance of this point from any other point given in the plane. This makes it possible (Prop. 1) to construct on a given line AB an equilateral triangle, by drawing first a circle with A as centre and AB as radius, and then a circle with B as centre and BA as radius. The point where these circles intersect—that they intersect Euclid quietly assumes—is the vertex of the required triangle. Euclid does not suppose, however, that a circle may be drawn which has its radius equal to the distance between any two points unless one of the points be the centre. This implies also that we are not supposed to be able to make any straight line equal to any other straight line, or to carry a distance about in space. Euclid therefore next solves the problem: It is required along a given straight line from a point in it to set off a distance equal to the length of another straight line given anywhere in the plane. This is done in two steps. It is shown in Prop. 2 how a straight line may be drawn from a given point equal in length to another given straight line not drawn from that point. And then the problem itself is solved in Prop. 3, by drawing first through the given point some straight line of the required length, and then about the same point as centre a circle having this length as radius. This circle will cut off from the given straight line a length equal to the required one. Now-a-days, instead of going through this long process, we take a pair of compasses and set off the given length by its aid. This assumes that we may move a length about without changing it. But Euclid has not assumed it, and this proceeding would be fully justified by his deare not to take for granted more than was necessary, if he were not obliged at his very next step actually to make this assumption, though without stating it.

§ 7. We now come (in Prop. 4) to the first theorem. It is the fundamental theorem of Euclid's whole system, there being only a very few propositions (like Props. 13, 14, 15, I.), except those in the 5th book and the first half of the 11th, which do not depend upon it. It is stated very accurately, though somewhat clumsily, as follows:—

If two triangles have two sides of the one equal to two sides of the other, each to each, and have also the angles contained by those sides equal to one another, they shall also have their bases or third sides equal; and the two triangles shall be equal; and their other angles shall be equal, each to each, namely, those to which the equal sides are opposite.

That is to say, the triangles are "identically" equal, and one may be considered as a copy of the other. The proof is very simple. The first triangle is taken up and placed on the second, so that the vertices of the triangles which are known to be equal fall upon each other. It is then easily seen that also the remaining parts of one coincide with those of the other, and that they are therefore equal. This process of applying one figure to another Euclid scarcely uses again, though many proofs would be simplified by doing so. The process introduces motion into geometry, and includes, as already stated, the axiom that figures may be moved without change of shape or size.

If the last proposition be applied to an isosceles triangle, which has two sides equal, we obtain the theorem (Prop. 5), *if two sides of a triangle are equal, then the angles opposite these sides are equal.*

Euclid's proof is somewhat complicated, and a stumbling-block to many schoolboys. The proof becomes much simpler if we consider the isosceles triangle ABC (AB=AC) twice over, once as a triangle BAC, and once as a triangle CAB: and now remember that

AB, AC in the first are equal respectively to AC, AB in the second, and the angles included by these sides are equal. Hence the triangles are equal, and the angles in the one are equal to those in the other, viz., those which are opposite equal sides, i.e., angle ABC in the first equals angle ACB in the second, as they are opposite the equal sides AC, and AB in the two triangles.

These follow the converse theorem (Prop. 6) *If two angles in a triangle are equal, then the sides opposite them are equal*—i.e., the triangle is isosceles. The proof given consists in what is called a *reductio ad absurdum*, a kind of proof often used by Euclid, and principally in proving the converse of a previous theorem. It assumes that the theorem to be proved is wrong, and then shows that this assumption leads to an absurdity, i.e., to a conclusion which is in contradiction to a proposition proved before—therefore the assumption made cannot be true, and hence that the theorem is true. It is often stated that Euclid invented this kind of proof, but the method is most likely much older.

§ 8. It is next proved that *two triangles which have the three sides of the one equal respectively to those of the other are identically equal, hence that the angles of the one are equal respectively to those of the other, those being equal which are opposite equal sides*. This is Prop. 8, Prop. 7 containing only a first step towards its proof.

These theorems allow now of the solution of a number of problems, viz. —

To bisect a given angle (Prop. 9)

To bisect a given finite straight line (Prop. 10).

To draw a straight line perpendicularly to a given straight line through a given point in it (Prop. 11), and also through a given point not in it (Prop. 12)

The solutions all depend upon properties of isosceles triangles § 9. The next three theorems relate to angles only, and might have been proved before Prop. 4, or even at the very beginning. The first (Prop. 13) says, *The angles which one straight line makes with another straight line on one side of it either are two right angles or are together equal to two right angles*. This theorem would have been unnecessary if Euclid had admitted the notion of an angle such that its two limits are in the same straight line, and had besides defined the sum of two angles.

Its converse (Prop. 14) is of great use, inasmuch as it enables us in many cases to prove that two straight lines drawn from the same point are one the continuation of the other. So also is

Prop. 15 *If two straight lines cut one another, the vertical or opposite angles shall be equal*. This theorem would have been unnecessary if Euclid had admitted the notion of an angle such that its two limits are in the same straight line, and had besides defined the sum of two angles.

§ 10. Euclid returns now to properties of triangles. Of great importance for the next steps (though afterwards superseded by a more complete theorem) is

Prop. 16 *If one side of a triangle be produced, the exterior angle shall be greater than either of the interior opposite angles*.

Prop. 17, *Any two angles of a triangle are together less than two right angles*, is an immediate consequence of it. By the aid of these two, the following fundamental properties of triangles are easily proved —

Prop. 18 *The greater side of every triangle has the greater angle opposite to it*;

Its converse, Prop. 19. *The greater angle of every triangle is subtended by the greater side, or has the greater side opposite to it*;

Prop. 20 *Any two sides of a triangle are together greater than the third side*;

And also Prop. 21 *If from the ends of the side of a triangle there be drawn two straight lines to a point within the triangle, these shall be less than the other two sides of the triangle, but shall contain a greater angle*.

§ 11. Having solved two problems (Props. 22, 23), he returns to two triangles which have two sides of the one equal respectively to two sides of the other. It is known (Prop. 4) that if the included angles are equal then the third sides are equal; and conversely (Prop. 8), if the third sides are equal, then the angles included by the first sides are equal. From this it follows that if the included angles are not equal, the third sides are not equal, and conversely, that if the third sides are not equal, the included angles are not equal. Euclid now completes this knowledge by proving that *if the included angles are not equal, then the third side in that triangle is the greater which contains the greater angle*; and conversely, that *if the third sides are unequal, that triangle contains the greater angle which contains the greater side*. These are Prop. 24 and Prop. 25.

§ 12. The next theorem (Prop. 26) says that *if two triangles have one side and two angles of the one equal respectively to one side and two angles of the other, viz., to both triangles either the angles adjacent to the equal side, or one angle adjacent and one angle opposite to it, then the two triangles are identically equal*.

This theorem belongs to a group with Prop. 4 and Prop. 8. Its first case might have been given immediately after Prop. 4, but the second case requires Prop. 16 for its proof.

§ 13. We come now to the investigation of parallel straight lines, i.e., of straight lines which lie in the same plane, and cannot be made to meet however far they be produced either way. The in-

vestigation, which starts from Prop. 16, will become clearer if a few names be explained which are not all used by Euclid. If two straight lines be cut by a third, the latter is now generally called a "transversal" of the figure. It forms at the two points where it cuts the given lines four angles with each. These of the angles which lie between the given lines are called interior angles, and of those, again, any two which lie on opposite sides of the transversal but one at each of the two points are called "alternate angles."

We may now state Prop. 16 thus — *If two straight lines which meet are cut by a transversal, their alternate angles are unequal*. For the lines will form a triangle, and one of the alternate angles will be an exterior angle to the triangle, the other interior and opposite to it.

From this follows at once the theorem contained in Prop. 27 *If two straight lines which are cut by a transversal make alternate angles equal, the lines cannot meet, however far they be produced, hence they are parallel*. This proves the existence of parallel lines.

Prop. 28 states the same fact in different forms *If a straight line, falling on two other straight lines, make the exterior angle equal to the interior and opposite angle on the same side of the line, or make the interior angles on the same side together equal to two right angles, the two straight lines shall be parallel to one another*.

Hence we know that, "if two straight lines which are cut by a transversal meet, then alternate angles are not equal," and hence that, "if alternate angles are equal, then the lines are parallel."

The question now arises, Are the propositions converse to those true or not? That is to say, "If alternate angles are unequal, do the lines meet?" And "if the lines are parallel, are alternate angles necessarily equal?"

The answer to either of these two questions implies the answer to the other. But it has been found impossible to prove that the negation or the affirmation of either is true.

The difficulty which thus arises is overcome by Euclid assuming that the first question has to be answered in the affirmative. This gives his last axiom (12), which we quote in his own words

AXIOM 12 — *If a straight line meet two straight lines, so as to make the two interior angles on the same side of it taken together less than two right angles, these straight lines, being continually produced, shall at length meet on that side on which are the angles which are less than two right angles*.

The answer to the second of the above questions follows from this, and gives the theorem Prop. 29. *If a straight line fall on two parallel straight lines, it makes the alternate angles equal to one another, and the exterior angle equal to the interior and opposite angle on the same side, and also the two interior angles on the same side together equal to two right angles*.

§ 14. With this a new part of elementary geometry begins. The earlier propositions are independent of this axiom, and would be true even if a wrong assumption had been made in it. They all relate to figures in a plane. But a plane is only one among an infinite number of conceivable surfaces. We may draw figures on any one of them and study their properties. We may, for instance, take a sphere instead of the plane, and obtain "spherical" in the place of "plane" geometry. If on one of these surfaces lines and figures could be drawn, answering to all the definitions of our plane figures, and if the axioms with the exception of the last all hold, then all propositions up to the 28th will be true for these figures. This is the case in spherical geometry if we substitute "shortest line" or "great circle" for "straight line," "small circle" for "circle," and if, besides, we limit all figures to a part of the sphere which is less than a hemisphere, so that two points on it cannot be opposite ends of a diameter, and therefore determine always one and only one great circle.

For spherical triangles, therefore, all the important propositions 4, 8, 26; 6 and 6, and 18, 19, and 20 will hold good.

This remark will be sufficient to show the impossibility of proving Euclid's last axiom, which would mean proving that this axiom is a consequence of the others, and hence that the theory of parallels would hold on a spherical surface, where the other axioms do hold, whilst parallels do not even exist.

It follows that the axiom in question states an inherent difference between the plane and other surfaces, and that the plane is only fully characterized when this axiom is added to the other assumptions.

§ 15. The introduction of the new axiom and of parallel lines leads to a new class of propositions.

After proving (Prop. 30) that *"two lines which are each parallel to a third are parallel to each other,"* we obtain the new properties of triangles contained in Prop. 32. Of these the second part is the most important, viz., the theorem, *The three interior angles of every triangle are together equal to two right angles*.

As easy deductions not given by Euclid but added by Simson follow the propositions about the angles in polygons, they are given in English editions as corollaries to Prop. 32.

These theorems do not hold for spherical figures. The sum of the interior angles of a spherical triangle is always greater than two right angles, and increases with the area.

§ 16 The theory of parallels as such may be said to be finished with Props. 33 and 34, which state properties of the parallelogram, *e. g.* of a quadrilateral formed by two pairs of parallels. They are—

Prop. 33 *The straight lines which join the extremities of two equal and parallel straight lines towards the same parts are themselves equal and parallel*, and

Prop. 34 *The opposite sides and angles of a parallelogram are equal to one another; and the diameter (diagonal) bisects the parallelogram, that is, divides it into two equal parts*.

§ 17 The rest of the first book relates to areas of figures

The theory is made to depend upon the theorems—

Prop. 35 *Parallelograms on the same base and between the same parallels are equal to one another*, and

Prop. 36 *Parallelograms on equal bases, and between the same parallels, are equal to one another*.

As each parallelogram is bisected by a diagonal, the last theorems hold also if the word parallelogram be replaced by "triangle," as is done in Props. 37 and 38.

It is to be remarked that Euclid proves these propositions only in the case when the parallelograms or triangles have their bases in the same straight line.

The theorems converse to the last form the contents of the next three propositions, viz.—

THEOREM (Props. 40 and 41).—*Equal triangles, on the same or on equal bases, in the same straight line, or on the same side of it, are between the same parallels.*

That the two cases here stated are given by Euclid in two separate propositions proved separately is characteristic of his method.

§ 18. To compare areas of other figures, Euclid shows first, in Prop. 42, how to draw a parallelogram which is equal in area to a given triangle, and has one of its angles equal to a given angle. If this given angle is right, then the problem is solved to draw a "rectangle" equal in area to a given triangle.

Next this parallelogram is transformed into another parallelogram, which has one of its sides equal to a given straight line, whilst its angles remain unaltered. This may be done by aid of the theorem in

Prop. 43 *The complements of the parallelograms which are about the diameter of any parallelogram are equal to one another*.

Thus the problem (Prop. 44) is solved to construct a parallelogram on a given line, which is equal in area to a given triangle, and which has one angle equal to a given angle (generally a right angle).

As every polygon can be divided into a number of triangles, we can now construct a parallelogram having a given angle, say a right angle, and being equal in area to a given polygon. For each of the triangles into which the polygon has been divided, a parallelogram may be constructed, having one side equal to a given straight line, and one angle equal to a given angle. If these parallelograms be placed side by side, they may be added together to form a single parallelogram, having still one side of the given length. This is done in Prop. 45.

Hence a means is found to compare areas of different polygons. We need only construct two rectangles equal in area to the given polygons, and having each one side of given length. By comparing the unequal sides we are enabled to judge whether the areas are equal, or which is the greater. Euclid does not state this consequence, but the problem is taken up again at the end of the second book, where it is shown how to construct a square equal in area to a given polygon.

§ 19. The first book concludes with one of the most important theorems in the whole of geometry, and one which has been celebrated since the earliest times. It is stated, but on doubtful authority, that Pythagoras discovered it, and it has been called by his name. If we call that side in a right-angled triangle which is opposite the right angle the hypotenuse, we may state it as follows—

THEOREM OF PYTHAGORAS (Prop. 47).—*In every right-angled triangle the square on the hypotenuse is equal to the sum of the squares of the other sides.*

And conversely—

Prop. 48 *If the square described on one of the sides of a triangle be equal to the squares described on the other sides, then the angle contained by these two sides is a right angle.*

On this theorem (Prop. 47) almost all geometrical measurement depends, which cannot be directly obtained.

BOOK II.

§ 20. The propositions in the second book are very different in character from those in the first; they all relate to areas of rectangles and squares. Their true significance is best seen by stating them in an algebraic form. This is often done by expressing the lengths of lines by aid of numbers, which tell how many times a chosen unit is contained in the lines. If there is a unit to be found which is contained an exact number of times in each side of a rectangle, it is easily seen, and generally shown in the teaching of arithmetic, that the rectangle contains a number of unit squares

equal to the product of the numbers which measure the sides, a unit square being the square on the unit line. If, however, no such unit can be found, this process requires that connexion between lines and numbers which is only established by aid of ratios of lines, and which is therefore at this stage altogether inadmissible. But there exists another way of connecting these propositions with algebra, based on modern notions which seem destined greatly to change and to simplify mathematics. We shall introduce here as much of it as is required for our present purpose.

At the beginning of the second book we find a definition according to which "a rectangle is said to be 'contained' by the two sides which contain one of its right angles"; in the text this phraseology is extended by speaking of rectangles contained by any two straight lines, meaning the rectangle which has two adjacent sides equal to the two straight lines.

We shall denote a finite straight line by a single small letter, a, b, c, \dots , and the area of the rectangle contained by two lines a and b by ab , and thus we shall call the product of the two lines a and b . It will be understood that this definition has nothing to do with the definition of a product of numbers.

We define as follows:—

The sum of two straight lines a and b means a straight line c which may be divided in two parts equal respectively to a and b . This sum is denoted by $a+b$.

The difference of two lines a and b (in symbols, $a-b$) means a line c which when added to b gives a , that is,

$$a-b=c \text{ if } b+c=a.$$

The product of two lines a and b (in symbols, ab) means the area of the rectangle contained by the lines a and b . For aa , which means the square on the line a , we write a^2 .

§ 21 The first ten of the fourteen propositions of the second book may then be written in the form of formulae as follows.—

- Prop. 1. $a(b+c+d+\dots) = ab+ac+ad+\dots$
2. $ab+ac=a^2$ if $b+c=a$.
3. $a(a+b) = a^2+ab$.
4. $(a+b)^2 = a^2+2ab+b^2$.
5. $(a+b)(a-b) = a^2-b^2$.
6. $(a+b)(a-b) = a^2-b^2$.
7. $a^2-(a-b)^2 = 2ab$.
8. $(a+b)^2 + b^2 = (2a+b)^2$.
9. $(a+b)^2 + (a-b)^2 = 2a^2+2b^2$.
10. $(a-b)^2 + (a-b)^2 = 2a^2+2b^2$.

It will be seen that 5 and 6, and also 9 and 10, are identical. In Euclid's statement they do not look the same, the figures being arranged differently.

If the letters a, b, c, \dots denoted numbers, it follows from algebra that each of these formulae is true. But this does not prove them in our case, where the letters denote lines, and their products areas without any reference to numbers. To prove them we have to discover the laws which rule the operations introduced, viz., addition and multiplication of segments. This we shall do now; and we shall find that these laws are the same with those which hold in algebraic addition and multiplication.

§ 22 In a sum of numbers we may change the order in which the numbers are added, and we may also add the numbers together in groups, and then add these groups. But this also holds for the sum of segments and for the sum of rectangles, as a little consideration shows. That the sum of rectangles has always a meaning follows from the Props. 43-45 in the first book. These laws about addition are reducible to the two—

$$\begin{aligned} a+b &= b+a & (1), \\ a+(b+c) &= (a+b)+c & (2), \end{aligned}$$

or, when expressed for rectangles,

$$\begin{aligned} ab+cd &= cd+ab & (3), \\ ab+(cd+ef) &= (ab+cd)+ef & (4). \end{aligned}$$

The brackets mean that the terms in the bracket have been added together before they are added to another term. The more general cases for more terms may be deduced from the above.

For the product of two numbers we have the law that it remains unaltered if the factors be interchanged. This also holds for our geometrical product. For if ab denotes the area of the rectangle which has a as base and b as altitude, then ba will denote the area of the rectangle which has b as base and a as altitude. But in a rectangle we may take either of the two lines which contain it as base, and then the other will be the altitude. Thus gives

$$ab=ba \quad (5).$$

In order further to multiply a sum by a number, we have in algebra the rule:—"Multiply each term of the sum, and add the products thus obtained." That this holds for our geometrical products is shown by Euclid in his first proposition of the second book, where he proves that the area of a rectangle whose base is the sum of a number of segments is equal to the sum of rectangles which have

This theorem may also be stated thus.—

Through three points only one circumference may be drawn; or, Three points determine a circle

Euclid does not give the theorem in this form. He proves, however, that the two circles cannot cut another in more than two points (Prop. 10), and that two circles cannot touch one another in more points than one (Prop. 18).

§ 30 Propositions 11 and 12 assert that if two circles touch, then the point of contact lies on the line joining their centres. This gives two propositions, because the circles may touch either internally or externally.

§ 31 Propositions 14 and 15 relate to the length of chords. The first says, that equal chords are equidistant from the centre, and that chords which are equidistant from the centre are equal.

Whilst Prop. 15 compares unequal chords, viz., *Of all chords the diameter is the greatest, and of other chords that is the greater which is nearer to the centre, and conversely, the greater chord is nearer to the centre.*

§ 32. In Prop. 16 the tangent to a circle is for the first time introduced. The proposition is meant to show that the straight line at the end point of the diameter, and at right angles to it is a tangent. The proposition itself does not state this. It runs thus—

Prop. 16 *The straight line drawn at right angles to the diameter of a circle, from the extremity of it, falls without the circle, and no straight line can be drawn from the extremity, between that straight line and the circumference, so as not to cut the circle.*

Corollary—The straight line at right angles to a diameter drawn through the end point of it touches the circle.

The statement of the proposition and its whole treatment show the difficulties which the tangents presented to Euclid.

Prop. 17 solves the problem *through a given point, either in the circumference or without it, to draw a tangent to a given circle.*

Closely connected with Prop. 16 are Props. 18 and 19, which state (Prop. 18), that the line joining the centre of a circle to the point of contact of a tangent is perpendicular to the tangent; and conversely (Prop. 19), that the straight line through the point of contact of, and perpendicular to, a tangent to a circle passes through the centre of the circle.

§ 33. The rest of the book relates to angles connected with a circle, viz., angles which have the vertex either at the centre or on the circumference, and which are called respectively angles at the centre and angles at the circumference. Between these two kinds of angles exists the important relation expressed as follows—

Prop. 20 *The angle at the centre of a circle is double of the angle at the circumference on the same base, that is, on the same arc.*

This is of great importance for its consequences, of which the two following are the principal:—

Prop. 21 *The angles in the same segment of a circle are equal to one another,*

And Prop. 22. *The opposite angles of any quadrilateral figure inscribed in a circle are together equal to two right angles.*

Further consequences are—

Prop. 23 *On the same straight line, and on the same side of it, there cannot be two similar segments of circles, not coinciding with one another;*

And Prop. 24. *Similar segments of circles on equal straight lines are equal to one another.*

The problem Prop. 25, *A segment of a circle being given to describe the circle of which it is a segment, may be solved much more easily and by the construction described in relation to Prop. 1, III., in § 27.*

§ 34. There follow four theorems connecting the angles at the centre, the arcs into which they divide the circumference, and the chords subtending these arcs. They are expressed for angles, arcs, and chords in equal circles, but they hold also for angles, arcs, and chords in the same circle.

The theorems are:—

Prop. 26. *In equal circles equal angles stand on equal arcs, whether they be at the centres or circumferences;*

Prop. 27 (converse to Prop. 26). *In equal circles the angles which stand on equal arcs are equal to one another, whether they be at the centres or the circumferences;*

Prop. 28 *In equal circles equal straight lines (equal chords) cut off equal arcs, the greater equal to the greater, and the less equal to the less;*

Prop. 29 (converse to Prop. 28). *In equal circles equal arcs are subtended by equal straight lines.*

§ 35. Other important consequences of Props. 20–22 are—

Prop. 31. *In a circle the angle in a semicircle is a right angle, but the angle in a segment greater than a semicircle is less than a right angle; and the angle in a segment less than a semicircle is greater than a right angle;*

Prop. 32. *If a straight line touch a circle, and from the point of contact a straight line be drawn cutting the circle, the angles which this line makes with the line touching the circle shall be equal to the angles which are in the alternate segments of the circle.*

§ 36 Propositions 30, 33, 34, contain problems which are solved by aid of the propositions preceding them.—

Prop. 30. *To bisect a given arc, that is, to divide it into two equal parts;*

Prop. 33. *On a given straight line to describe a segment of a circle containing an angle equal to a given rectilineal angle;*

Prop. 34. *From a given circle to cut off a segment containing an angle equal to a given rectilineal angle.*

§ 37. If we draw chords through a point A within a circle, they will each be divided by A into two segments. Between these segments the law holds that the rectangle contained by them has the same area on whatever chord through A the segments are taken. The value of this rectangle changes, of course, with the position of A.

A similar theorem holds if the point A be taken without the circle. On every straight line through A, which cuts the circle in two points B and C, we have two segments AB and AC, and the rectangles contained by them are again equal to one another, and equal to the square on a tangent drawn from A to the circle.

The first of these theorems gives Prop. 35, and the second Prop. 36, with its corollary, whilst Prop. 37, the last of Book III, gives the converse to Prop. 36. The first two theorems may be combined in one:—

THEOREM—*If through a point A in the plane of a circle a straight line be drawn cutting the circle in B and C, then the rectangle AB.AC has a constant value so long as the point A be fixed; and if from A a tangent AD can be drawn to the circle, touching at D, then the above rectangle equals the square on AD.*

Prop. 37 may be stated thus—

THEOREM—*If from a point A without a circle a line be drawn cutting the circle in B and C, and another line to a point D on the circle, and if AB.AC=AD², then the line AD touches the circle at D.*

It is not difficult to prove also the converse to the general proposition as above stated. It may be expressed as follows:—

If four points A B C D be taken on the circumference of a circle, and if the lines AB, CD, produced if necessary, meet at E, then

$$EA \cdot EB = EC \cdot ED;$$

and conversely, if this relation holds then the four points lie on a circle, that is, the circle drawn through three of them passes through the fourth.

That a circle may always be drawn through three points, provided that they do not be in a straight line, is proved only later on in Book IV.

BOOK IV.

§ 38 The fourth book contains only problems, all relating to the construction of triangles and polygons inscribed in and circumscribed about circles, and of circles inscribed in or circumscribed about triangles and polygons. They are nearly all given for their own sake, and not for future use in the construction of figures, as are most of those in the former books. In seven definitions at the beginning of the book it is explained what is understood by figures inscribed in or described about other figures, with special reference to the case where one figure is a circle. Instead, however, of saying that one figure is described about another, it is now generally said that the one figure is circumscribed about the other. We may then state the definitions 3 or 4 thus—

Definition—A polygon is said to be inscribed in a circle, and the circle is said to be circumscribed about the polygon, if the vertices of the polygon lie in the circumference of the circle.

And definitions 5 and 6 thus—

Definition—A polygon is said to be circumscribed about a circle, and a circle is said to be inscribed in a polygon, if the sides of the polygon are tangents to the circle.

§ 39 The first problem is merely constructive. It requires to draw in a given circle a chord equal to a given straight line, which is not greater than the diameter of the circle. The problem is not a determinate one, inasmuch as the chord may be drawn from any point in the circumference. This may be said of almost all problems in this book, especially of the next two. They are:—

Prop. 2. *In a given circle to inscribe a triangle equiangular to a given triangle;*

Prop. 3. *About a given circle to circumscribe a triangle equiangular to a given triangle*

§ 40. Of somewhat greater interest are the next problems, where the triangles are given and the circles to be found.

Prop. 4. *To inscribe a circle in a given triangle.*

The result is that the problem has always a solution, viz., the centre of the circle is the point where the bisectors of two of the interior angles of the triangle meet. The solution shows, though Euclid does not state this, that the problem has but one solution; and also,

THEOREM—*The three bisectors of the interior angles of any triangle*

met is a point, and this is the centre of the circle inscribed in the triangle.

The solutions of most of the other problems contain also theorems Of these we shall state those which are of special interest. Euclid does not state any one of them.

§ 41 Prop. 5 To circumscribe a circle about a given triangle.

The one solution which always exists contains the following:—
THEOREM.—The three straight lines which bisect the sides of a triangle at right angles meet in a point, and this point is the centre of the circle circumscribed about the triangle.

Euclid adds in a corollary the following property:—

The centre of the circle circumscribed about a triangle lies within, on a side of, or without the triangle, according as the triangle is acute-angled, right-angled, or obtuse-angled.

§ 42 Whilst it is always possible to draw a circle which is inscribed in, or circumscribed about a given triangle, this is not the case with quadrilaterals or polygons of more sides. Of these for which this is possible the regular polygons are the most interesting. In each of them a circle may be inscribed, and another may be circumscribed about it.

Euclid does not use the word regular, but he describes the polygons in question as *equiangular* and *equilateral*. We shall use the name regular polygon. The regular triangle is equilateral, the regular quadrilateral is the square.

Euclid considers the regular polygons of 4, 5, 6, and 15 sides. For each of the first three he solves the problems—(1) to inscribe such a polygon in a given circle; (2) to circumscribe it about a given circle; (3) to inscribe a circle in, and (4) to circumscribe a circle about, such a polygon.

For the regular triangle the problems are not repeated, because more general problems have been solved.

Props. 6, 7, 8, and 9 solve these problems for the square.

The general problem of inscribing in a given circle a regular polygon of n sides depends upon the problem of dividing the circumference of a circle into n equal parts, or what comes to the same thing, of drawing from the centre of the circle n radii such that the angles between consecutive radii are equal, that is, to divide the space about the centre into n equal angles. Thus, if it is required to inscribe a square in a circle, we have to draw four lines from the centre, making the four angles equal. This is done by drawing two diameters at right angles to one another. The ends of these diameters are the vertices of the required square. If, on the other hand, tangents be drawn at these ends, we obtain a square circumscribed about the circle.

§ 43. To construct a regular pentagon, we find it convenient first to construct a regular decagon. This requires to divide the space about the centre into ten equal angles. Each will be $\frac{1}{10}$ th of a right angle, or $\frac{1}{20}$ th of two right angles. If we suppose the decagon constructed, and if we join the centre to the end of one side, we get an isosceles triangle, where the angle at the centre angles $\frac{1}{10}$ th of two right angles; hence each of the angles at the base will be $\frac{1}{20}$ th of two right angles, as all three angles together equal two right angles. Thus we have to construct an isosceles triangle, having the angle at the vertex equal to half an angle at the base. This is solved in Prop. 10, by aid of the problem in Prop. 11 of the second book. If we make the sides of this triangle equal to the radius of the given circle, then the base will be the side of the regular decagon inscribed in the circle. This side being known the decagon can be constructed, and if the vertices are joined alternately, leaving out half their number, we obtain the regular pentagon.

Euclid does not proceed thus. He wants the pentagon before the decagon. This, however, does not change the real nature of his solution, nor does his solution become simpler by not mentioning the decagon.

Once the regular pentagon is inscribed, it is easy to circumscribe another by drawing tangents at the vertices of the inscribed pentagon. This is shown in Prop. 12.

Prop. 13 and 14 teach how a circle may be inscribed in or circumscribed about any given regular pentagon.

§ 44. The regular hexagon is more easily constructed, as shown in Prop. 15. The result is that the side of the regular hexagon inscribed in a circle is equal to the radius of the circle.

For this polygon the other three problems mentioned are not solved.

§ 45. The book closes with Prop. 16. To inscribe a regular quindecagon in a given circle. That this may be done is easily seen. If we inscribe a regular pentagon and a regular hexagon in the circle, having one vertex in common, then the arc from the common vertex to the next vertex of the pentagon is $\frac{1}{5}$ th of the circumference, and to the next vertex of the hexagon is $\frac{1}{6}$ th of the circumference. The difference between these arcs is, therefore, $\frac{1}{30}$ th of the circumference. The latter may, therefore, be divided into thirty, and hence also into fifteen equal parts, and the regular quindecagon be described.

§ 46. We conclude with a few theorems about regular polygons which are not given by Euclid.

THEOREM.—The straight lines perpendicular to and bisecting the

sides of any regular polygon meet in a point. The straight lines bisecting the angles in the regular polygon meet in the same point. This point is the centre of the circles circumscribed about and inscribed in the regular polygon. The proof, which is easy, is left to the reader.

We can bisect any given arc (Prop. 30, III.) Hence we can divide a circumference into 2n equal parts as soon as it has been divided into n equal parts, or as soon as a regular polygon of n sides has been constructed. Hence—

THEOREM.—If a regular polygon of n sides has been constructed, then a regular polygon of 2n sides, of 4n, of 8n sides, &c., may also be constructed. Euclid shows how to construct regular polygons of 3, 4, 5, and 15 sides. It follows that we can construct regular polygons of

3,	6,	12,	24...	sides
4,	8,	16,	32.	"
6,	10,	20,	40.	"
15,	30,	60,	120.	"

The construction of any new regular polygon not included in one of these series will give rise to a new series. Till the beginning of this century nothing was added to the knowledge of regular polygons as given by Euclid. Gauss, in his celebrated *Disquisitiones*, proved that every regular polygon of $2^n + 1$ sides may be constructed if this number $2^n + 1$ be prime, and that no others can be constructed by elementary methods. This shows that regular polygons of 7, 9, 13 sides cannot thus be constructed, but that a regular polygon of 17 sides is possible; for $2^4 + 1 = 17$. The next polygon is one of 257 sides. The construction becomes already rather complicated for 17 sides.

BOOK V.

§ 47. The fifth book of the *Elements* is not exclusively geometrical. It contains the theory of ratios and proportion of quantities in general. The treatment, as here given, is admirable, and in every respect superior to the algebraical method by which Euclid's theory is now generally replaced. It has, however, the reputation of being too difficult for schools, and is therefore very seldom read. We shall try to make the subject clear, and to show why the usual algebraical treatment of proportion is not really sound. We begin by quoting those definitions at the beginning of Book V. which are most important. These definitions have given rise to much discussion.

The only definitions which are essential for the fifth book are Defs. 1, 2, 4, 5, 6, and 7. Of the remainder 3, 8, and 9 are more or less useless, and probably not Euclid's, but additions of later editors, of whom Theon of Alexandria was the most prominent. Defs. 10 and 11 belong rather to the sixth book, whilst all the others are merely nominal. The really important ones are 4, 5, 6, and 7.

§ 48. To define a magnitude is not attempted by Euclid. The first two definitions state what is meant by a "part," that is, a submultiple or measure, and by a "multiple" of a given magnitude. The meaning of Def. 4 is that two given quantities can have a ratio to one another only in case that they are comparable as to their magnitude, that is, if they are of the same kind.

Def. 8, which is probably due to Theon, professes to define a ratio, but is as meaningless as it is unneeded, for, for all that is wanted is given in Defs. 5 and 7.

In Def. 5 it is explained what is meant by saying that two magnitudes have the same ratio to one another as two other magnitudes, and in Def. 7 what we have to understand by a greater or a less ratio. The 6th definition is only nominal, explaining the meaning of the word *proportion*.

Euclid represents magnitudes by lines, and often denotes them either by single letters or, like lines, by two letters. We shall use only single letters for the purpose. If a and b denote two magnitudes of the same kind, their ratio will be denoted by $a : b$; if c and d are two other magnitudes of the same kind, but possibly of a different kind from a and b , then if a and d have the same ratio to one another as a and b , this will be expressed by writing—

$$a : b :: c : d.$$

Further, if m is a (whole) number, ma shall denote the multiple of a which is obtained by taking it m times.

§ 49. The whole theory of ratios is based on Def. 5.

Def. 5. The first of four magnitudes is said to have the same ratio to the second that the third has to the fourth when, any equimultiples whatever of the first and the third being taken, and any equimultiples whatever of the second and the fourth, if the multiple of the first be less than that of the second, the multiple of the third is also less than that of the fourth; and if the multiple of the first is equal to that of the second, the multiple of the third is also equal to that of the fourth; and if the multiple of the first is greater than that of the second, the multiple of the third is also greater than that of the fourth.

It will be well to show at once in an example how this definition can be used, by proving the first part of the first proposition in the sixth book. *Triangles of the same altitude are to one another as their bases, or if a and b are the bases, and α and β the areas, of two triangles which have the same altitude, then $a : b :: \alpha : \beta$.*

To prove this, we have, according to Definition 5, to show—

$$\begin{aligned} \text{if } ma > nb, & \text{ then } m\alpha > n\beta, \\ \text{if } ma = nb, & \text{ then } m\alpha = n\beta, \\ \text{if } ma < nb, & \text{ then } m\alpha < n\beta \end{aligned}$$

That this is true is in our case easily seen. We may suppose that the triangles have a common vertex, and their bases in the same line. We set off the base a along the line containing the bases m times, we then join the different parts of division to the vertex, and get m triangles all equal to a . The triangle on ma as base equals, therefore, $m\alpha$. If we proceed in the same manner with the base b , setting it off n times, we find that the area of the triangle on the base nb equals $n\beta$, the vertex of all triangles being the same. But if two triangles have the same altitude, then their areas are equal if the bases are equal, hence $ma = nb$ if $ma = nb$, and if their bases are unequal, then that has the greater area which is on the greater base, in other words, ma is greater than, equal to, or less than nb , according as ma is greater than, equal to, or less than nb , which was to be proved.

§ 50. It will be seen that even in this example it does not become evident what a ratio really is. It is still an open question whether ratios are magnitudes which we can compare. We do not know whether the ratio of two lines is a magnitude of the same kind as the ratio of two areas. Though we might say that Def. 5 defines *equal* ratios, still we do not know whether they are equal in the sense of the axiom, that two things which are equal to a third are equal to one another. That this is the case requires a proof, and until this proof is given we shall use the $::$ instead of the sign $=$, which, however, we shall afterwards introduce.

As soon as it has been established that all ratios are like magnitudes, it becomes easy to show that, in some cases at least, they are numbers. This step was never made by Greek mathematicians. They distinguished always most carefully between continuous magnitudes and the discrete series of numbers. In modern times it has become the custom to ignore this difference.

If, in determining the ratio of two lines, a common measure can be found, which is contained m times in the first, and n times in the second, then the ratio of the two lines equals the ratio of the two numbers $m:n$. This is shown by Euclid in Prop. 5, X. But the ratio of two numbers is, as a rule, a fraction, and the Greeks did not, as we do, consider fractions as numbers. Far less had they any notion of introducing irrational numbers, which are neither whole nor fractional, as we are obliged to do if we wish to say that all ratios are numbers. The incommensurable numbers which are thus introduced as ratios of incommensurable quantities are now as days as familiar to us as fractions; but a proof is generally omitted that we may apply to them the rules which have been established for rational numbers only. Euclid's treatment of ratios avoids this difficulty. His definitions holds for commensurable as well as for incommensurable quantities. Even the notion of incommensurable quantities is avoided in Book V. But he proves that the more elementary rules of algebra hold for ratios. We shall state all his propositions in that algebraical form to which we are now accustomed. This may, of course, be done without changing the character of Euclid's method.

§ 51. Using the notation explained above we express the first propositions as follows:—

Prop. 1. If $a = ma'$, $b = mb'$, $c = mc'$,
then $a + b + c = m(a' + b' + c')$.

Prop. 2. If $a = mb$, and $c = md$,
 $e = nb$, and $f = nd$,

then $a + c$ is the same multiple of b as $c + f$ is of d , viz.:

$$a + c = (m + n)b, \text{ and } c + f = (m + n)d.$$

Prop. 3. If $a = mc$, $c = md$, then is na the same multiple of b that nc is of d , viz., $na = nm$, $nc = nm$.

Prop. 4. If $a : b :: c : d$,
then $ma : mb :: mc : md$.

Prop. 5. If $a = mb$, and $c = md$,
then $a - c = m(b - d)$.

Prop. 6. If $a = mb$, $c = md$,

then are $a - nb$ and $c - nd$ either equal to, or equimultiples of, b and d , viz., $a - nb = (m - n)b$ and $c - nd = (m - n)d$, where $m - n$ may be unity.

All these propositions relate to *equimultiples*. Now follow propositions about ratios which are compared as to their magnitude.

§ 52. Prop. 7. If $a = b$, then $a : c :: b : c$ and $c : a :: c : b$. The proof is simply this. As $a = b$ we know that $ma = mb$;

therefore if $ma > mb$, then $mb > na$,
if $ma = mb$, then $mb = na$,
if $ma < mb$, then $mb < na$.

therefore the first proportion holds by Definition 5.

Prop. 8. If $a > b$, then $a : c > b : c$,
and $a : c < b : c$.

The proof depends on Definition 7.

Prop. 9 (converse to Prop. 7). If

$a : c :: b : c$, then $a = b$.

Prop. 10 (converse to Prop. 8). If

$a : c > b : c$, then $a > b$,
and if $a : c < b : c$, then $a < b$.

Prop. 11. If $a : b :: c : d$,
and $a : b :: c : f$,
then $c : d :: c : f$.

In words, *if two ratios are equal to a third, they are equal to one another*. After these propositions have been proved, we have a right to consider a ratio as a *magnitude*, for only now can we consider a ratio as something for which the axiom about magnitudes holds, things which are equal to a third are equal to one another.

We shall indicate this by writing in future the sign $=$ instead of $::$. The remaining propositions, which explain themselves, may then be stated as follows:—

§ 53. Prop. 12. If $a : b :: c : d$, $e : f$,
then $a + c + e : b + d + f :: a : b$.

Prop. 13. If $a : b :: c : d$, and $c : d > e : f$,
then $a : b > e : f$.

Prop. 14. If $a : b :: c : d$, and $c : d < e : f$, then $a : b < e : f$.

Prop. 15. Magnitudes have the same ratio to one another that their equimultiples have—

$$ma : mb = a : b.$$

Prop. 16. If a, b, c, d are magnitudes of the same kind, and if

$$\begin{aligned} a : b &= c : d, \\ a : c &= b : d, \end{aligned}$$

then $a + b : b :: b + c : c$,
and $a - b : b :: b - c : c$.

Prop. 17. If $a + b : b :: c + d : d$,
then $a : b :: c : d$.

Prop. 18 (converse to 17). If $a : b :: c : d$,
then $a + b : b :: c + d : d$.

Prop. 19. If a, b, c, d are quantities of the same kind, and if

$$\begin{aligned} a : b &= c : d, \\ a - c &= b - d, \end{aligned}$$

then $a : b :: c : d$.
§ 54. Prop. 20. *If there be three magnitudes, and other three, which have the same ratio, taken two and two, then if the first be greater than the third, the fourth shall be greater than the sixth; and if equal, equal, and if of less, less.*

If we indicate by

$$a : b :: c : d :: e : f :: g : h :: i : j :: k : l :: m : n :: o : p :: q : r :: s : t :: u : v :: w : x :: y : z ::$$

that the ratio of any two consecutive magnitudes on the first side equals that of the corresponding magnitudes on the second side, we may write this theorem in symbols, thus:—

If a, b, c be quantities of one, and d, e, f magnitudes of the same or any other kind, such that

$$\begin{aligned} a : b &= c : d :: e : f, \\ \text{and if } a &> b, \text{ then } c > d, \\ \text{but if } a &= b, \text{ then } c = d, \\ \text{and if } a &< b, \text{ then } c < d, \end{aligned}$$

Prop. 21. If $a : b :: e : f$, and $b : c :: d : e$,
or if $a : b :: c : d :: e : f$,
and if $a > b$, then $c > d$,
but if $a = b$, then $c = d$,
and if $a < b$, then $c < d$.

By aid of these two propositions the following two are proved.
§ 55. Prop. 22. *If there be any number of magnitudes, and as many others, which have the same ratio, taken two and two in order, the first shall have to the last of the first magnitudes the same ratio which the first of the others has to the last.*

We may state it more generally, thus:—

$$\text{If } a : b :: c : d :: e : f :: g : h :: i : j :: k : l :: m : n :: o : p :: q : r :: s : t :: u : v :: w : x :: y : z ::$$

then not only have two consecutive, but any two magnitudes on the first side, the same ratio as the corresponding magnitudes on the other. For instance—

$$a : c :: d : f :: e : g :: h : i :: j : k :: l : m :: n : o :: p : q :: r : s :: t : u :: v : w :: x : y :: z : \dots$$

Prop. 23 we state only in symbols, viz:—

$$\text{If } a : b :: c : d :: e : f :: g : h :: i : j :: k : l :: m : n :: o : p :: q : r :: s : t :: u : v :: w : x :: y : z ::$$

then

$$\begin{aligned} a.c &= c'.a', \\ b.c &= c'.b', \end{aligned}$$

and so on.

Prop 24 comes to this: If $a = b = c$ and $c = b = f$, then

$$a + c = b + f = d.$$

Some of the propositions which are considered in the above propositions have special names. These we have omitted, as being of no use, since algebra has enabled us to bring the difficult operations contained in the propositions under a common point of view.

§ 56 The last proposition in the fifth book is of a different character.

Prop. 25. If four magnitudes of the same kind be proportional, the greatest and least of them together shall be greater than the other two together. In symbols—

If a, b, c, d be magnitudes of the same kind, and if $a : b = c : d$, and if a is the greatest, hence d the least, then $a + d > b + c$.

§ 57 We return once again to the question, What is a ratio? We have seen that we may treat ratios as magnitudes, and that all ratios are magnitudes of the same kind, for we may compare any two as to their magnitude. It will presently be shown that ratios of lines may be considered as quotients of lines, so that a ratio appears as answer to the question, How often is one line contained in another? But the answer to this question is given by a number, at least in some cases, and in all cases if we admit incommensurable numbers. Considered from this point of view, we may say the fifth book of the *Elements* shows that some of the simplest algebraical operations hold for incommensurable numbers. In the ordinary algebraical treatment of numbers this proof is altogether omitted, or given by a process of limits which does not seem to be natural to the subject.

BOOK VI.

§ 53. The sixth book contains the theory of similar figures. After a few definitions explaining terms, the first proposition gives the first application of the theory of proportion.

Prop. 1. Triangles and parallelograms of the same altitude are to one another as their bases.

The proof has already been considered in § 49.

From this follows easily the important theorem

Prop. 2. If a straight line be drawn parallel to one of the sides of a triangle, it shall cut the other sides, or those sides produced, proportionally; and if the sides or the sides produced be cut proportionally, the straight line which joins the points of section, shall be parallel to the remaining side of the triangle.

§ 59. The next proposition, together with one added by Simson as Prop. A, may be expressed more conveniently if we introduce a modern phraseology, viz. if in a line AB we assume a point C between A and B , we shall say that C divides AB internally in the ratio $AC : CB$; but if C be taken in the line AB produced, we shall say that AB is divided externally in the ratio $AC : CB$.

The two propositions then come to this

THEOREM (Prop. 3).—The bisector of an angle in a triangle divides the opposite side internally in a ratio equal to the ratio of the two sides including that angle; and conversely, if a line through the vertex of a triangle divide the base internally in the ratio of the two other sides, then that line bisects the angle at the vertex.

THEOREM (Simson's Prop. A).—The line which bisects an exterior angle of a triangle divides the opposite side externally in the ratio of the other sides; and conversely, if a line through the vertex of a triangle divide the base externally in the ratio of the sides, then it bisects an exterior angle at the vertex of the triangle.

If we combine both we have—

THEOREM.—The two lines which bisect the interior and exterior angles at one vertex of a triangle divide the opposite side internally and externally in the same ratio, viz. in the ratio of the other two sides.

§ 60. The next four propositions contain the theory of similar triangles, of which four cases are considered. They may be stated together.

THEOREM.—Two triangles are similar,—

1. (Prop. 4.) If the triangles are equiangular;

2. (Prop. 5.) If the sides of the one are proportional to those of the other;

3. (Prop. 6.) If two sides in one are proportional to two sides in the other, and if the angles contained by these sides are equal;

4. (Prop. 7.) If two sides in one are proportional to two sides in the other, if the angles opposite homologous sides are equal, and if the angles opposite the other homologous sides are both acute, both right, or both obtuse; homologous sides being in each case those which are opposite equal angles.

An important application of these theorems is at once made to a right-angled triangle, viz. —

Prop. 8. In a right-angled triangle, if a perpendicular be drawn from the right angle to the base, the triangles on each side of it are similar to the whole triangle, and to one another.

Corollary.—From this it is manifest that the perpendicular drawn from the right angle of a right-angled triangle to the base is a mean proportional between the segments of the base, and also that each of the sides is a mean proportional between the base and the segment of the base adjacent to that side.

§ 61 There follow four propositions containing problems, viz. in language slightly different from Euclid's—

Prop. 9. To divide a straight line into a given number of equal parts.

Prop. 10. To divide a straight line in a given ratio.

Prop. 11. To find a third proportional to two given straight lines.

Prop. 12. To find a fourth proportional to three given straight lines.

Prop. 13. To find a mean proportional between two given straight lines.

The last three may be written as equations with one unknown quantity—viz. if we call the given straight lines a, b, c , and the required line x , we have to find a line x so that

$$\text{Prop. 11. } a : b = b : x;$$

$$\text{Prop. 12. } a : b = c : x;$$

$$\text{Prop. 13. } a : x = x : b.$$

We shall see presently how these may be written without the signs of ratios.

§ 62 Euclid considers next propositions connected with parallelograms and triangles which are equal in area.

Prop. 14. Equal parallelograms which have one angle of the one equal to one angle of the other have their sides about the equal angles reciprocally proportional; and parallelograms which have one angle of the one equal to one angle of the other, and their sides about the equal angles reciprocally proportional, are equal to one another.

Prop. 15. Equal triangles which have one angle of the one equal to one angle of the other, have their sides about the equal angles reciprocally proportional; and triangles which have one angle of the one equal to one angle of the other, and their sides about the equal angles reciprocally proportional, are equal to one another.

The latter proposition is really the same as the former, for if, as in the accompanying diagram, in the figure

belonging to the former the two equal parallelograms AB and BC be bisected by the lines DF and EG , and if EF be drawn, we get the figure belonging to the latter.

It is worth noting that the lines FE and DG are parallel.

We may state therefore the theorem—

THEOREM.—If two triangles are equal in area, and have one angle in the one vertically opposite to one angle in the other, then the two straight lines which join the remaining two vertices of the one to those of the other triangle are parallel.

§ 63. A most important theorem is

Prop. 16. If four straight lines be proportionals, the rectangle contained by the extremes is equal to the rectangle contained by the means; and if the rectangle contained by the extremes be equal to the rectangle contained by the means, the four straight lines are proportionals.

In symbols, if a, b, c, d are the four lines, and

if $a : b = c : d$,
then $ad = bc$;
and conversely, if $ad = bc$,
then $a : b = c : d$,

where ad and bc denote (as in § 20), the areas of the rectangles contained by a and d and by b and c respectively.

This allows us to transform every proportion between four lines into an equation between two products.

It shows further that the operation of forming a product of two lines, and the operation of forming their ratio are each the inverse of the other.

If we now define a quotient $\frac{a}{b}$ of two lines as the number which multiplied into b gives a , so that

$$\frac{a}{b} \cdot b = a,$$

we see that from the equality of two quotients

$$\frac{a}{b} = \frac{c}{d}$$

follows, if we multiply both sides by bd ,

$$\begin{aligned} \frac{a}{b} \cdot b \cdot d &= \frac{c}{d} \cdot b \cdot d, \\ ad &= cb. \end{aligned}$$

But from this it follows according to the last theorem that

$$a \cdot b = c \cdot d$$

Hence we conclude that the quotient $\frac{a}{b}$ and the ratio $a : b$ are different forms of the same magnitude, only with this important difference that the quotient $\frac{a}{b}$ would have a meaning only if a and b have a common measure, until we introduce incommensurable numbers, while the ratio $a : b$ has always a meaning, and thus gives rise to the introduction of incommensurable numbers.

Thus it is really the theory of ratios in the fifth book which enables us to extend the geometrical calculus given before in connection with Book II. It will also be seen that if we write the ratios in Book V as quotients, or rather as fractions, then most of the theorems state properties of quotients or of fractions.

§ 64. Prop. 17 contains only a special case of 16. After the problem, Prop. 18. *On a given straight line to describe a rectilinear figure similar and similarly situated to a given rectilinear figure*, there follows another fundamental theorem.

Prop. 19. *Similar triangles are to one another in the duplicate ratio of their homologous sides*. In other words, the areas of similar triangles are to one another as the squares on homologous sides. This is generalized in

Prop. 20. *Similar polygons may be divided into the same number of similar triangles, having the same ratio to one another that the polygons have, and the polygons are to one another in the duplicate ratio of their homologous sides*.

§ 65. Prop. 21. *Rectilinear figures which are similar to the same rectilinear figure are also similar to each other*, is an immediate consequence of the definition of similar figures. As similar figures may be said to be equal in "shape" but not in "size," we may state it also thus

"Figures which are equal in shape to a third are equal in shape to each other."

Prop. 22. *If four straight lines be proportionals, the similar rectilinear figures similarly described on them shall also be proportionals; and if the similar rectilinear figures similarly described on four straight lines be proportionals, these straight lines shall be proportionals*.

This is essentially the same as the following:—

If
then

$$\frac{a}{b} = \frac{c}{d}, \quad \frac{a}{c} = \frac{b}{d}.$$

§ 66. Now follows a proposition which has been much discussed with regard to Euclid's exact meaning in saying that a ratio is compounded of two other ratios, viz.

Prop. 23. *Parallelisms which are equiangular to one another, have to one another the ratio which is compounded of the ratios of their sides*.

The proof of the proposition makes its meaning clear. In symbols the ratio $a : c$ is compounded of the two ratios $a : b$ and $b : c$, and if $a : b = a' : b'$, $b : c = b' : c'$, then $a : c$ is compounded of $a' : b'$ and $b' : c'$.

If we consider the ratios as numbers, we may say that the one ratio is the product of those of which it is compounded, or in symbols,

$$\frac{a}{c} = \frac{a}{b} \cdot \frac{b}{c} = \frac{a'}{b'} \cdot \frac{b'}{c'}; \text{ if } \frac{a}{b} = \frac{a'}{b'} \text{ and } \frac{b}{c} = \frac{b'}{c'}.$$

The theorem in Prop. 23 is the foundation of all mensuration of areas. From it we see at once that two rectangles have the ratio of their areas compounded of the ratios of their sides.

If A is the area of a rectangle contained by a and b , and B that of a rectangle contained by c and d , so that $A = ab$, $B = cd$, then $A : B = ab : cd$, and this is, the theorem says, compounded of the ratios $a : c$ and $b : d$. In forms of quotients,

$$\frac{a}{c} \cdot \frac{b}{d} = \frac{ab}{cd}.$$

This shows how to multiply quotients in our geometrical calculus. Further, *Two triangles have the ratios of their areas compounded of the ratios of their bases and their altitude*. For a triangle is equal in area to half a parallelogram which has the same base and the same altitude.

To bring these theorems to the form in which they are usually given, we assume a straight line u as our unit of length (generally an inch, a foot, a mile, &c.), and determine the number a which expresses how often u is contained in a line a , so that a denotes the ratio $a : u$ whether commensurable or not, and that $a = au$. We call this number a the numerical value of a . If in the same manner β be the numerical value of a line b we have

$$a : b = a : \beta;$$

in words: *The ratio of two lines (and of two like quantities in general) is equal to that of their numerical values*.

This is easily proved by observing that $a = au$, $b = \beta u$, therefore $a : b = a\beta u : \beta u$, and this may without difficulty be shown to equal $a : \beta$.

If now a, b be base and altitude of one, a', b' those of another parallelogram, α, β and α', β' their numerical values respectively, and A, A' then areas, then

$$\frac{A}{A'} = \frac{a}{a'} \cdot \frac{b}{b'} = \frac{\alpha}{\alpha'} \cdot \frac{\beta}{\beta'} = \frac{\alpha\beta}{\alpha'\beta'}.$$

In words: *The areas of two parallelograms are to each other as the products of the numerical values of their bases and altitudes*.

If especially the second parallelogram is the unit square, $\alpha' c$, a square on the unit of length, then $\alpha' = \beta' = 1$, $A' = u^2$, and we have

$$\frac{A}{A'} = \alpha\beta. \text{ or } A = \alpha\beta \cdot u^2$$

This gives the theorem. The number of unit squares contained in a parallelogram equals the product of the numerical values of base and altitude, and similarly the number of unit squares contained in a triangle equals half the product of the numerical values of base and altitude.

This is often stated by saying that the area of a parallelogram is equal to the product of the base and the altitude, meaning by this product the product of the numerical values, and not the product as defined above in § 20.

§ 68. Propositions 24 and 26 relate to parallelograms about diagonals, such as are considered in Book I, 43. They are—

Prop. 24. *Parallelograms about the diameter of any parallelogram are similar to the whole parallelogram and to one another; and its converse* (Prop. 28). *If two similar parallelograms have a common angle, and be similarly situated, they are about the same diameter*.

Between these is inserted a problem.

Prop. 25. *To describe a rectilinear figure which shall be similar to one given rectilinear figure, and equal to another given rectilinear figure*.

§ 69. Prop. 27 contains a theorem relating to the theory of maxima and minima. We may state it thus:

Prop. 27. *If a parallelogram be divided into two by a straight line cutting the base, and if on half the base another parallelogram be constructed similar to one of those parts, then this third parallelogram is greater than the other part*.

Of far greater interest than this general theorem is a special case of it, where the parallelograms are changed into rectangles, and where one of the parts into which the parallelogram is divided is made a square, for then the theorem changes into one which is easily recognized to be identical with the following—

THEOREM.—*Of all rectangles which have the same perimeter the square has the greatest area*.

This may also be stated thus:—

THEOREM.—*Of all rectangles which have the same area the square has the least perimeter*.

§ 70. The next three propositions contain problems which may be said to be solutions of quadratic equations. The first two are, like the last, involved in somewhat obscure language. We transcribe them as follows—

Problem.—*To describe on a given base a parallelogram, and to divide it either internally (Prop. 28) or externally (Prop. 29) from a point on the base into two parallelograms, of which the one has a given size (is equal in area to a given figure), whilst the other has a given shape (is similar to a given parallelogram)*.

If we express this again in symbols, calling the given base a , the one part x , and the altitude y , we have to determine x and y in the first case from the equations

$$(a-x)y = k^2,$$

$$\frac{x}{y} = \frac{p}{q},$$

k^2 being the given size of the first, and p and q the base and altitude of the parallelogram which determine the shape of the second of the required parallelograms.

If we substitute the value of y , we get

$$(a-x)x = \frac{pk^2}{q},$$

or,

$$ax - x^2 = b^2,$$

where a and b are known quantities, taking $b^2 = \frac{pk^2}{q}$.

The second case (Prop. 29) gives rise, in the same manner, to the quadratic

$$ax + x^2 = b^2.$$

The next problem—

Prop. 30. *To cut a given straight line in extreme and mean ratio*, leads to the equation

$$ax + x^2 = a^2.$$

This is, therefore, only a special case of the last, and is, besides, an old acquaintance, being essentially the same problem as that proposed in II. 11.

Prop. 30 may therefore be solved in two ways, either by aid of Prop. 29 or by aid of II. 11. Euclid gives both solutions.

§ 71 Prop. 31 (Theorem). *In any right-angled triangle, any rectilinear figure described on the side subtending the right angle is equal to the similar and similarly-described figures on the sides containing the right angle*,—is a pretty generalization of the theorem of Pythagoras (I. 47).

Leaving out the next proposition, which is of little interest, we come to the last in this book.

Prop. 33. *In equal circles angles, whether at the centres or the circumferences, have the same ratio which the arcs on which they stand have to one another; so also have the sectors.*

Of this, the part relating to angles at the centre is of special importance, it enables us to measure angles by arcs.

With this closes that part of the *Elements* which is devoted to the study of figures in a plane.

BOOK XI

§ 72 In this book figures are considered which are not confined to a plane, viz., first relations between lines and planes in space, and afterwards properties of solids.

Of new definitions we mention those which relate to the perpendicularity and the inclination of lines and planes.

Def. 3. *A straight line is perpendicular to, or at right angles, to a plane when it makes right angles with every straight line meeting it in that plane.*

The definition of perpendicular planes (Def. 4) offers no difficulty. Euclid defines the inclination of lines to planes and of planes to planes (Defs. 5 and 6) by aid of plane angles, included by straight lines, with which we have been made familiar in the first books.

The other important definitions are those of parallel planes, which never meet (Def. 8), and of solid angles formed by three or more planes meeting in a point (Def. 9).

To these we add the definition of a line parallel to a plane as a line which does not meet the plane.

§ 73. Before we investigate the contents of Book XI., it will be well to recapitulate shortly what we know of planes and lines from the definitions and axioms of the first book. These a plane has been defined as a surface which has the property that every straight line which joins two points in it lies altogether in it. This is equivalent to saying that a straight line which has two points in a plane has all points in the plane. Hence, a straight line which does not lie in the plane cannot have more than one point in common with the plane. This is virtually the same as Euclid's Prop. 1, viz. —

Prop. 1 *One part of a straight line cannot be in a plane and another part without it.*

It also follows, as was pointed out in § 3, in discussing the definitions of Book I., that a plane is determined already by one straight line and a point without it, viz., if all lines be drawn through the point, and cutting the line, they will form a plane.

This may be stated thus:—

A plane is determined—

- 1st, *By a straight line and a point which does not lie on it;*
- 2d, *By three points which do not lie in a straight line; for if two of these points be joined by a straight line we have case 1;*
- 3d, *By two intersecting straight lines; for the point of intersection and two other points, one in each line, give case 2;*
- 4th, *By two parallel lines (Def. 35, 1).*

The third case of this theorem is Euclid's

Prop. 2. *Two straight lines which cut one another are in one plane, and three straight lines which meet one another are in one plane.*

And the fourth is Euclid's

Prop. 7. *If two straight lines be parallel, the straight line drawn from any point in one to any point in the other is in the same plane with the parallels.* From the definition of a plane further follows:—

Prop. 8 *If two planes cut one another, their common section is a straight line.*

§ 74 Whilst these propositions are virtually contained in the definition of a plane, the next gives us a new and fundamental property of space, showing at the same time that it is possible to have a straight line perpendicular to a plane, according to Def. 3. It states—

THEOREM (Prop. 4).—*If a straight line is perpendicular to two straight lines in a plane which it meets, then it is perpendicular to all lines in the plane which it meets, and hence it is perpendicular to the plane.*

Def. 3 may be stated thus: If a straight line is perpendicular to a plane, then it is perpendicular to every line in the plane which it meets. The converse to this would be.

THEOREM.—*All straight lines which meet a given straight line in the same point, and are perpendicular to it, lie in a plane which is perpendicular to that line.*

This Euclid states thus:

Prop. 5. *If three straight lines meet all at one point, and a straight*

line stands at right angles to each of them at that point, the three straight lines shall be in one and the same plane.

§ 75 There follow theorems relating to the theory of parallel lines in space, viz. —

THEOREM (Prop. 6).—*Any two lines which are perpendicular to the same plane are parallel to each other, and conversely.*

THEOREM (Prop. 8).—*If of two parallel straight lines one is perpendicular to a plane, the other is so also.*

Further, the important theorems—

Prop. 9. *Two straight lines which are each of them parallel to the same straight line, and not in the same plane with it, are parallel to one another, where the words, "and not in the same plane with it" may be left out, for they exclude the case of three parallels in a plane, which has been proved before; and*

THEOREM (Prop. 10).—*If two angles in different planes have the two limits of the one parallel to those of the other, then the angles are equal. That their planes are parallel is shown later on in Prop. 15. This theorem is not necessarily true, for the angles in question may be supplementary; but then the one angle will be equal to that which is adjacent and supplementary to the other, and this latter angle will also have its limits parallel to those of the first.*

From this theorem it follows that if we take any two straight lines in space which do not meet, and if we draw through any point P in space two lines parallel to them, then the angle included by these lines will always be the same, whatever the position of the point P may be. This angle has in modern times been called the angle between the given lines:—

DEFINITION.—*By the angles between two not intersecting lines we understand the angles which two intersecting lines include that are parallel respectively to the two given lines.*

§ 76. It is now possible to solve the following two problems. —

PROBLEM.—*To draw a straight line perpendicular to a given plane from a given point which lies*

1. *Not in the plane* (Prop. 11).

2. *In the plane* (Prop. 12).

The second case is easily reduced to the first—viz., if by aid of the first we have drawn any perpendicular to the plane from some point without it, we need only draw through the given point in the plane a line parallel to it, in order to have the required perpendicular given. The solution of the first part is of interest in itself. It depends upon a construction which may be expressed as a theorem.

THEOREM.—*If from a point A without a plane a perpendicular AB be drawn to the plane, and if from the foot B of this perpendicular another perpendicular BC be drawn to any straight line in the plane, then the straight line joining A to the foot C of this second perpendicular will also be perpendicular to the line in the plane.*

The theory of perpendiculars to a plane is concluded by the theorem—

Prop. 13. *Through any point in space, whether in or without a plane, only one straight line can be drawn perpendicular to the plane.*

§ 77. The next four propositions treat of parallel planes. It is shown that planes which have a common perpendicular are parallel (Prop. 14); that two planes are parallel if two intersecting straight lines in the one are parallel respectively to two straight lines in the other plane (Prop. 16); that parallel planes are cut by any plane in parallel straight lines (Prop. 16); and lastly, that any two straight lines are cut proportionally by a series of parallel planes (Prop. 17).

This theory is made more complete by adding the following theorems, which are easy deductions from the last.—*Two parallel planes have common perpendiculars (Prop. 14); and Two planes which are parallel to a third plane are parallel to each other.*

It will be noted that Prop. 15 at once allows of the solution of the problem: "Through a given point to draw a plane parallel to a given plane." And it is also easily proved that this problem allows always of one, and only of one, solution.

§ 78. We come now to planes which are perpendicular to one another. Two theorems relate to them.

Prop. 18. *If a straight line be at right angles to a plane, every plane which passes through it shall be at right angles to that plane.*

Prop. 19. *If two planes which cut one another be each of them perpendicular to a third plane, their common section shall be perpendicular to the same plane.*

§ 79. If three planes pass through a common point, and if they bound each other, a solid angle of three faces, or a trihedral angle, is formed, and similarly by more planes a solid angle of more faces, or a polyhedral angle. These have many properties which are quite analogous to those of triangles and polygons in a plane. Euclid states some, viz. —

Prop. 20. *If a solid angle be contained by three plane angles, any two of them are together greater than the third.*

But the next—

Prop. 21. *Every solid angle is contained by plane angles, which are together less than four right angles—has no analogous theorem in the plane.*

We may mention, however, that the theorems about triangles contained in the propositions of Book I, which do not depend upon the theory of parallels (that is all up to Prop 27), have their corresponding theorems about trihedral angles. The latter are formed, if for "side of a triangle" we write "plane angle" or "face" of trihedral angle, and for "angle of triangle" we substitute "angle between two faces" where the planes containing the solid angle are called its *faces*. We get, for instance, from I 4, the theorem, *If two trihedral angles have the angles of two faces in the one equal to the angles of two faces in the other, and have likewise the angles included by these faces equal, then the angles in the remaining faces are equal, and the angles between the other faces are equal each to each, viz, those which are opposite equal faces.* The solid angles themselves are not necessarily equal, for they may be only symmetrical like the right hand and the left.

The connexion indicated between triangles and trihedral angles will also be recognized in

Prop 22 *If every two of three plane angles be greater than the third, and if the straight lines which contain them be all equal, a triangle may be made of the straight lines that join the extremities of those equal straight lines.*

And Prop. 23 solves the problem, *To construct a trihedral angle having the angles of its faces equal to three given plane angles, any two of them being greater than the third.* It is, of course, analogous to the problem of constructing a triangle having its sides of given length.

Two other theorems of this kind are added by Simson in his edition of Euclid's Elements

§ 80 These are the principal properties of lines and planes in space, but, before we go on to their applications it will be well to define the word *distance*. In geometry distance means always "shortest distance"; viz, the distance of a point from a straight line, or from a plane, is the length of the perpendicular from the point to the line or plane. The distance between two non-intersecting lines is the length of their common perpendicular, there being but one. The distance between two parallel lines or between two parallel planes is the length of the common perpendicular between the lines or the planes.

§ 81. *Parallelepipeds*.—The rest of the book is devoted to the study of the parallelepiped. In Prop. 24 the possibility of such a solid is proved, viz

Prop. 24. *If a solid be contained by six planes two and two of which are parallel, the opposite planes are similar and equal parallelograms.*

Euclid calls this solid henceforth a parallelepiped, though he never defines the word. Either face of it may be taken as *base*, and its distance from the opposite face as *altitude*.

Prop 25. *If a solid parallelepiped be cut by a plane parallel to two of its opposite planes, it divides the whole into two solids, the base of one of which shall be to the base of the other as the one solid is to the other.*

The ratio here corresponds to the theorem (VI 1) that parallelograms between the same parallels are to one another as their bases. A similar analogy is to be observed among a number of the remaining propositions.

§ 82. After solving a few problems we come to

Prop. 28 *If a solid parallelepiped be cut by a plane passing through the diagonals of two of the opposite planes, it shall be cut in two equal parts.*

In the proof of this, as of several other propositions, Euclid neglects the difference between solids which are symmetrical like the right hand and the left.

Prop. 31. *Solid parallelepipeds, which are upon equal bases, and of the same altitude, are equal to one another.*

Props. 29 and 30 contain special cases of this theorem leading up to the proof of the general theorem.

As consequences of this fundamental theorem we get

Prop. 32 *Solid parallelepipeds, which have the same altitude, are to one another as their bases*, and Prop 33, *Similar solid parallelepipeds are to one another in the triplicate ratio of their homologous sides.* If we consider, as in § 67, the ratios of lines as numbers, we may also say—

The ratio of the volumes of similar parallelepipeds is equal to the ratio of the third powers of homologous sides.

Parallelepipeds which are not similar but equal are compared by aid of the theorem

Prop. 34. *The bases and altitudes of equal solid parallelepipeds are reciprocally proportional; and if the bases and altitudes be reciprocally proportional, the solid parallelepipeds are equal.*

§ 83. Of the following propositions the 37th and 40th are of special interest.

Prop. 37 *If four straight lines be proportionals, the similar solid parallelepipeds, similarly described from them, shall also be proportionals*, and if the similar parallelepipeds similarly described from four straight lines be proportionals, the straight lines shall be proportionals.

In symbols it says—

$$\text{If } a : b :: c : d, \text{ then } a^3 : b^3 :: c^3 : d^3$$

Prop 40 teaches how to compare the volumes of triangular prisms with those of parallelepipeds, by proving that *a triangular prism is equal in volume to a parallelepiped, which has the same altitude and its base equal to the altitude and the base of the triangular prism.*

§ 84. From these propositions follow all results relating to the mensuration of volumes. We shall state these as we did in the case of areas. The starting-point is the "rectangular" parallelepiped, which has every edge perpendicular to the planes it meets, and which takes the place of the rectangle in the plane. If this has all its edges equal we obtain the "cube."

If we take a certain line u as unit length, then the square on u is the unit of area, and the cube on u the unit of volume, that is to say, if we wish to measure a volume we have to determine how many unit cubes it contains.

A rectangular parallelepiped has, as a rule, the three edges unequal, which meet at a point. Every other edge is equal to one of them. If a, b, c be the three edges meeting at a point, then we may take the rectangle contained by two of them, say by b and c , as base and the third as altitude. Let V be its volume, V' that of another rectangular parallelepiped which has the edges a', b, c , hence the same base as the first. It follows then easily, from Prop 25 or 32, that $V : V' = a : a'$, or in words,

Rectangular parallelepipeds on equal bases are proportional to their altitudes.

If we have two rectangular parallelepipeds, of which the first has the volume V and the edges a, b, c , and the second, the volume V' and the edges a', b', c' , we may compare them by aid of two new ones which have respectively the edges a', b, c , and a, b', c , and the volumes V_1 and V_2 . We then have

$$V : V_1 = a : a' ; V_1 : V_2 = b : b' ; V_2 : V' = c : c'.$$

Compounding these, we have

$$V : V' = (a : a') (b : b') (c : c'),$$

$$\text{or } \frac{V}{V'} = \frac{a}{a'} \cdot \frac{b}{b'} \cdot \frac{c}{c'}.$$

Hence, as a special case, making V' equal to the unit cube U on u we get

$$\frac{V}{U} = \frac{a}{u} \cdot \frac{b}{u} \cdot \frac{c}{u} = a \cdot b \cdot c.$$

where a, b, c are the numerical values of a, b, c ; that is, *The number of unit cubes in a rectangular parallelepiped is equal to the product of the numerical values of its three edges.* This is generally expressed by saying the volume of a rectangular parallelepiped is measured by the product of its sides, or by the product of its base into its altitude, which in this case is the same.

Prop. 31 allows us to extend this to any parallelepipeds, and Props. 28 or 40 to triangular prisms

THEOREM.—*The volume of any parallelepiped, or of any triangular prism, is measured by the product of base and altitude.*

The consideration that any polygonal prism may be divided into a number of triangular prisms, which have the same altitude and the sum of their bases equal to the base of the polygonal prism, shows further that the same holds for any prism whatever.

BOOK XIII.

§ 85. In the last part of Book XI we have learnt how to compare the volumes of parallelepipeds and of pyramids. In order to determine the volume of any solid bounded by plane faces we must determine the volume of pyramids, for every such solid may be decomposed into a number of pyramids.

As every pyramid may again be decomposed into triangular pyramids, it becomes only necessary to determine their volume. This is done by the

Theorem.—*Every triangular pyramid is equal in volume to one third of a triangular prism having the same base and the same altitude as the pyramid.*

This is an immediate consequence of Euclid's

Prop. 7. *Every prism having a triangular base may be divided into three pyramids that have triangular bases, and are equal to one another.*

The proof of this theorem is difficult, because the three triangular pyramids into which the prism is divided are by no means equal in shape, and cannot be made to coincide. It has first to be proved that two triangular pyramids have equal volumes, if they have equal bases and equal altitudes. This Euclid does in the following manner. He first shows (Prop. 8) that a triangular pyramid may be divided into four parts, of which two are equal triangular pyramids similar to the whole pyramid, whilst the other two are equal triangular prisms, and further, that these two prisms together are greater than the two pyramids, hence more than half the given pyramid. He next shows (Prop. 4) that if two triangular pyra-

nuds are given, having equal bases and equal altitudes, and if each be divided as above, then the two triangular prisms in the one are equal to those in the other, and each of the remaining pyramids in the one has its base and altitude equal to the base and altitude of the remaining pyramids in the other. Hence to these pyramids the same process is again applicable. We are thus enabled to cut out of the two given pyramids equal parts, each greater than half the original pyramid. Of the remainder we can again cut out equal parts greater than half these remainders, and so on as far as we like. This process may be continued till the last remainder is smaller than any assignable quantity, however small. It follows, so we should conclude at present, that the two volumes must be equal, for they cannot differ by any assignable quantity.

To Greek mathematicians this conclusion offers far greater difficulties. They prove elaborately, by a *reductio ad absurdum*, that the volumes cannot be unequal. This proof must be read in the *Elements*. A further discussion of this method of exhaustion, as it is called, would belong to a treatise on the history of geometry. We refer readers to Hankel, *Geschichte der Mathematik* (p. 115 sq). We must, however, state that we have in the above not proved Euclid's Prop. 5, but only a special case of it. Euclid does not suppose that the bases of the two pyramids to be compared are equal, and hence he proves that the volumes are as the bases. The reasoning of the proof becomes clearer in the special case, from which the general one may be easily deduced.

§ 86. Prop. 6 extends the result to pyramids with polygonal bases. From these results follow again the rules at present given for the mensuration of solids, viz., a pyramid is the third part of a triangular prism having the same base and the same altitude. But a triangular prism is equal in volume to a parallelepiped which has the same base and altitude. Hence if B is the base and h the altitude, we have

$$\text{Volume of prism} = Bh,$$

$$\text{Volume of pyramid} = \frac{1}{3} Bh,$$

statements which have to be taken in the sense that B means the number of square units in the base, h the number of units of length in the altitude, or that B and h denote the numerical values of base and altitude.

§ 87. A method, similar to that used in proving Prop. 5 leads to the following results relating to solids bounded by simple curved surfaces.—

Prop. 10. Every cone is the third part of a cylinder which has the same base, and is of an equal altitude with it.

Prop. 11. Cones and cylinders of the same altitude are to one another as their bases.

Prop. 12. Similar cones and cylinders have to one another the triplicate ratio of that which the diameters of their bases have.

Prop. 13. If a cylinder be cut by a plane parallel to its opposite planes or bases, it divides the cylinder into two cylinders, one of which is to the other as the axis of the first to the axis of the other; which may also be stated thus—

Cylinders on the same base are proportional to their altitudes.

Prop. 14. Cones and cylinders upon equal bases are to one another as their altitudes.

Prop. 15. The bases and altitudes of equal cones and cylinders are reciprocally proportional, and if the bases and altitudes be reciprocally proportional, the cones and cylinders are equal to one another.

These theorems again lead to formulae in mensuration, if we compare a cylinder with a prism having its base and altitude equal to the base and altitude of the cylinder. This may be done by the method of exhaustion. We get, then, the result that their bases are equal, and have, if B denotes the numerical value of the base, and h that of the altitude,

$$\text{Volume of cylinder} = Bh,$$

$$\text{Volume of cone} = \frac{1}{3} Bh.$$

§ 88. The remaining propositions relate to circles and spheres. Of the sphere only one property is proved, viz.—

Prop. 18. Spheres have to one another the triplicate ratio of that which their diameters have. The mensuration of the sphere, like that of the cone, the cylinder, and the cone, had not been settled in the time of Euclid. It was done by Archimedes.

BOOK XIII.

§ 89. The 13th and last book of Euclid's *Elements* is devoted to the regular solids. It is shown that there are five of them, viz. :—

1. The regular tetrahedron, with 4 triangular faces and 4 vertices;
2. The cube, with 8 vertices and 6 square faces;
3. The octahedron, with 6 vertices and 8 triangular faces;
4. The dodecahedron, with 12 pentagonal faces, 3 at each of the 20 vertices;
5. The icosahedron, with 20 triangular faces, 5 at each of the 12 vertices.

It is shown how to inscribe these solids in a given sphere, and how to determine the lengths of their edges.

These results are—if r denotes the radius of the circumscribed sphere, and a the side of the regular solid—

$$\text{For tetrahedron} \quad a^2 = \frac{8}{3} r^2,$$

$$,, \text{ octahedron} \quad a^2 = 2r^2,$$

$$,, \text{ hexahedron or cube} \quad a^2 = \frac{4}{3} r^2,$$

$$,, \text{ icosahedron} \quad a^2 = 2 \left(1 - \frac{\sqrt{5}}{5} \right) r^2,$$

$$,, \text{ dodecahedron} \quad a^2 = 2 \left(1 - \frac{\sqrt{5}}{8} \right) r^2.$$

§ 90. The 13th book, and therefore the *Elements*, conclude with the scholium, "that no other regular solid exists besides the five ones enumerated."

The proof is very simple. Each face is a regular polygon, hence the angles of the faces at any vertex must be angles in equal regular polygons, must be together less than four right angles (XI. 21), and must be three or more in number. Each angle in a regular triangle equals two-thirds of one right angle. Hence it is possible to form a solid angle with three, four, or five regular triangles or faces. These give the solid angles of the tetrahedron, the octahedron, and the icosahedron. The angle in a square (the regular quadrilateral) equals one right angle. Hence three will form a solid angle, that of the cube, and four will not. The angle in the regular pentagon equals $\frac{2}{5}$ of a right angle. Hence three of them equal $\frac{18}{5}$ (i.e., less than 4) right angles, and form the solid angle of the dodecahedron. Three regular polygons of six or more sides cannot form a solid angle. Therefore no other regular solids are possible.

SECTION II.—HIGHER OR PROJECTIVE GEOMETRY.

It is difficult, at the outset, to characterize Projective Geometry as compared with Euclidian. But a few examples will at least indicate the difference between the two.

In Euclid's *Elements* almost all propositions refer to the magnitude of lines, angles, areas, or volumes, and therefore to measurement. The statement that an angle is right, or that two straight lines are parallel, refers to measurement. On the other hand, the fact that a straight line does or does not cut a circle is independent of measurement, it being dependent only upon the mutual "position" of the line and the circle. This difference becomes clearer if we project any figure from one plane to another. By thus the length of lines, the magnitude of angles and areas, is altered, so that the projection, or shadow, of a square on a plane will not be a square, it will, however, be some quadrilateral. Again, the projection of a circle will not be a circle, but some other curve more or less resembling a circle. But one property may be stated at once,—no straight line can cut the projection of a circle in more than two points, because no straight line can cut a circle in more than two points. There are, then, some properties of figures which do not alter by projection, whilst others do. To the latter belong nearly all properties relating to measurement, at least in the form in which they are generally given. The others are said to be projective properties, and their investigation forms the subject of Projective Geometry.

Different are the kinds of properties investigated in the old and the new sciences, the methods followed differ in a still greater degree. In Euclid each proposition stands by itself; its connexion with others is never indicated; the leading ideas contained in its proof are not stated; general principles do not exist. In the modern methods, on the other hand, the greatest importance is attached to the leading thoughts which pervade the whole; and general principles, which bring whole groups of theorems under one aspect, are given rather than separate propositions. The whole tendency is towards generalization. A straight line is considered as given in its entirety, extending both ways to infinity, while Euclid

is very careful never to admit anything but finite quantities. The treatment of the infinite is in fact another fundamental difference between the two methods. Euclid avoids it. In modern geometry it is systematically introduced, for only thus is generality obtained.

Of the different modern methods of geometry, we shall treat principally of the methods of projection and correspondence which have proved to be the most powerful. These have become independent of Euclidian Geometry, especially through the *Geometrie der Lage* of V. Standt, and the *Ausdehnungslehre* of Grassmann.

For the sake of brevity we shall presuppose a knowledge of Euclid's *Elements*, although we shall use only a few of his propositions.

§ 1. We consider space as filled with points, lines, and planes, and these we call the elements out of which our figures are to be formed, calling any combination of these elements a "figure."

By a line we mean a straight line in its entirety, extending both ways to infinity; and by a plane, a plane surface, extending in all directions to infinity. We suppose

That through any two points in space one and only one line may be drawn (Eucl. I, Def. 4, Ax. 10, Post. 2).

That through any three points which are not in a line, one and only one plane may be placed (compare p. 386, § 73, above). That the intersection of two planes is a line (Eucl. XI 13); That a line which has two points in common with a plane lies in the plane (Eucl. I, Def. 7), hence that the intersection of a line and a plane is a single point; and

That three planes which do not meet in a line have one single point in common.

These results may be stated differently in the following form. —

- | | |
|---|--|
| I. A plane is determined— | A point is determined— |
| 1. By three points which do not lie in a line; | 1. By three planes which do not pass through a line; |
| 2. By two intersecting lines; | 2. By two intersecting lines; |
| 3. By a line and a point which does not lie in it | 3. By a line and a plane which does not pass through it. |

II. A line is determined—

- | | |
|-------------------|-------------------|
| 1. By two points, | 2. By two planes. |
|-------------------|-------------------|

The reader will observe that not only are planes determined by points, but also points by planes; that therefore we have a right to consider the planes as elements, like points, and also that in any one of the above statements we may interchange the words point and plane, and we obtain again a correct statement, provided that these statements themselves are true. As they stand, we ought, in several cases, to add "if they are not parallel," or some such words, parallel lines and planes being evidently left altogether out of consideration. To correct this we have to reconsider the theory of parallels.

§ 2. Let us take in a plane α a line p (fig. 1), a point S not in this line, and a line q drawn through S . Then this line q will meet the line p in a point A . If we turn the line q about S towards q' , its point of intersection with p will move along p towards B , passing, on continued turning, to a greater and greater distance, until it is moved out of our reach. If we turn q still farther, its continuation will meet p , but now at the other side of A . The point of intersection has disappeared to the right and reappeared to the left. There is one intermediate position where q is parallel to p —that is where it does not cut p .

In every other position it cuts p in some finite point. If, on the other hand, we move the point A to an infinite distance in p , then the line q which passes through A will be a line which does not cut p at any finite point. Thus we are led to say: Every line through S which joins it to any point at an infinite distance in p is parallel to p . But by Euclid's 12th axiom there is but one line parallel to p through S . The difficulty in which we are thus involved is due to the fact that we try to reason about infinity as if we, with our finite capabilities, could comprehend the infinite. To overcome this difficulty, we may say that all points at infinity in a line appear to us as one, and may be replaced by a single "ideal" point, just as all points in a fixed star—which is not at an infinite, only at a great distance—cannot be distinguished by us and to beings on the earth count as

Fig. 1.

one. We may therefore now give the following definitions and axiom —

Definition — Lines which meet at infinity are called parallel. *Axiom* — All points at an infinite distance in a line may be considered as one single point.

Definition — This ideal point is called the point at infinity in the line.

The axiom is equivalent to Euclid's Axiom 12, for it follows from either that through any point only one line may be drawn parallel to a given line.

This point at infinity in a line is reached whether we move a point in the one or in the opposite direction of a line to infinity. A line thus appears closed by this point, and we speak as if we could move a point along the line from one position A to another B in two ways, either through the point at infinity or through finite points only.

It must never be forgotten that this point at infinity is ideal, that the results based on this assumption are true for that finite region of space which is within our reach, and that beyond this region they may or may not be true, — we do not know.

The advantage of this view of parallels will become apparent at every step as we go on.

§ 3. Having thus arrived at the notion of replacing all points at infinity in a line by one ideal point, there is no difficulty in replacing all points at infinity in a plane by one ideal line.

To make this clear, let us suppose that a line p , which cuts two fixed lines a and b in the points A and B , moves parallel to itself to a greater and greater distance. It will at last cut both a and b at their points at infinity, so that a line which joins the two points at infinity in two intersecting lines lies altogether at infinity. Every other line in the plane will meet it therefore at infinity, and thus it contains all points at infinity in the plane.

All points at infinity in a plane lie in a line, which is called the line at infinity in the plane.

It follows that parallel planes must be considered as planes having a common line at infinity, for any other plane cuts them in parallel lines (Eucl. XI. 16), which have a point at infinity in common.

If we next take two intersecting planes, then the point at infinity in their line of intersection lies in both planes, so that their lines at infinity meet. Hence every line at infinity meets every other line at infinity, and they are therefore all in one plane.

All points at infinity in space may be considered as lying in one ideal plane, which is called the plane at infinity.

§ 4. We have now the following definitions —

Parallel lines are lines which meet at infinity; Parallel planes are planes which meet at infinity. A line is parallel to a plane if it meets it at infinity. Theorems like thus—Lines (or planes) which are parallel to a third are parallel to each other—follow at once.

This view of parallels leads therefore to no contradiction of Euclid's *Elements*.

As immediate consequences we get the propositions: —

- Every line meets a plane in one point, or it lies in it;
- Every plane meets every other plane in a line;
- Any two lines in the same plane meet.

§ 5. We have called points, lines, and planes the elements of geometrical figures. We also say that an element of one kind contains one of the other if it lies in it or passes through it.

All the elements of one kind which are contained in one or two elements of a different kind form aggregates which have to be enumerated. They are the following. —

- I. Of one dimension.
 1. The *row*, or range, of points formed by all points in a line, which is called its base.
 2. The *flat pencil* formed by all the lines through a point in a plane. Its base is the point in the plane.
 3. The *axial pencil* formed by all planes through a line which is called its base or axis.
- II. Of two dimensions.
 1. The field of points and lines—that is, a plane with all its points and all its lines.
 2. The pencil of lines and planes—that is, a point in space with all lines and all planes through it.
- III. Of three dimensions.
 - The space of points—that is, all points in space.
 - The space of planes—that is, all planes in space.
- IV. Of four dimensions.
 - The space of lines, or all lines in space.

§ 6. The word dimension in the above needs explanation.

If a plane we take a row p and a pencil with centre Q , then through every point in p one line in the pencil will pass, and every ray in Q will cut p in one point, so that we are entitled to say a row contains as many points as a flat pencil lines, and we may add, as an axial pencil planes, because an axial pencil is cut by a plane in a flat pencil.

The number of elements in the row, in the flat pencil, and in the

axial pencil is, of course, infinite and indefinite too, but the same in all. For a moment we shall treat it as being a definite number which we denote by c . Then a plane contains c^2 points and as many lines. To see this, take a flat pencil in a plane. It contains c lines, and each line contains c points, whilst each point in the plane lies on one of these lines. Similarly, in a plane each line cuts a fixed line in a point. But this line is cut at each point by c lines and contains c points; hence there are c^2 lines in a plane.

A pencil in space contains as many lines as a plane contains points and as many planes as a plane contains lines, for any plane cuts the pencil in a field of points and lines. Hence a pencil contains c^2 lines and c^2 planes. *The field and the pencil are of two dimensions.*

To count the number of points in space we observe that each point lies on some line in a pencil. But the pencil contains c^2 lines, and each line c points, hence space contains c^3 points. Each plane contains any fixed plane in a line. But a plane contains c^2 lines, and through each pass c planes, therefore space contains c^3 planes.

Hence space contains as many planes as points, but it contains an infinite number of times more lines than points or planes. To count them, notice that every line cuts a fixed plane in one point. But c^2 lines pass through each point, and there are c^2 points in the plane. Hence there are c^4 lines in space. *The space of points and planes is of three dimensions, but the space of lines is of four dimensions.*

A field of points or line contains an infinite number of rows and flat pencils, a pencil contains an infinite number of flat pencils and of axial pencils; space contains a triple infinite number of pencils and of fields, c^4 rows and axial pencils, and c^4 flat pencils—or, in other words, each point is a centre of c^4 flat pencils.

§ 7. The above enumeration allows a classification of figures.

Figures in a row consist of groups of points only, and figures in the flat or axial pencil consist of groups of lines or planes. In the plane we may draw polygons, and in the pencil or in the point, solid angles, and so on.

We may also distinguish the different measurements. We have—

- In the row, length of segment;
- In the flat pencil, angles;
- In the axial pencil, dihedral angles between two planes;
- In the plane, areas;
- In the pencil, solid angles;
- In the space of points or planes, volumes.

SEGMENTS OF A LINE.

§ 8. Any two points A and B in space determine on the line through them a finite part, which may be considered as being described by a point moving from A to B. This we shall denote by AB, and distinguish it from BA, which is supposed as being described by a point moving from B to A, and hence in a direction or in a "sense" opposite to AB. Such a finite line, which has a definite sense, we shall call a "segment," so that AB and BA denote different segments, which are said to be equal in length but of opposite sense. The one sense is often called positive and the other negative.

In introducing the word "sense" for direction in a line, we have the word direction reserved for direction of the line itself, so that different lines have different directions, unless they be parallel, whilst in each line we have a positive and negative sense.

We may also say, with Professor Clifford, that AB denotes the "ray" of going from A to B.

§ 9. If we now have three points A, B, C in a line (fig. 2), the step AB will bring us from A to B, and the step BC from B to C. Hence both steps are equivalent to the one step AC. This is expressed by saying that AC is the "sum" of AB and BC; in symbols—

$$AB + BC = AC,$$

where account is to be taken of the sense.

This equation is true whatever be the position of the three points on the line. As a special case we have

$$AB + BA = 0 \quad \dots \dots \dots (1),$$

and similarly

$$AB + BC + CA = 0 \quad \dots \dots \dots (2),$$

which again is true for any three points in a line.

We further write

$$AB = -BA,$$

where — denotes negative sense.

We can then, just as in algebra, change subtraction of segments into addition by changing the sense, so that $AB - CD$ is the same as $AB + (-CD)$ or $AB + BC$. A figure will at once show the truth of this. The sense is, in fact, in every respect equivalent to the "sign" of a number in algebra.

§ 10. Of the many formulae which exist between points in a line we shall have to use only one more, which connects the segments between any four points A, B, C, D in a line. We have—

$$\begin{aligned} BC &= BD + DC, \\ CA &= CD + DA, \\ AB &= AD + DB, \end{aligned}$$

or multiplying these by AD, BD, CD respectively, we get—

$$\begin{aligned} BC \cdot AD &= BD \cdot AD + DC \cdot AD = BD \cdot AD - CD \cdot AD \\ CA \cdot BD &= CD \cdot BD + DA \cdot BD = CD \cdot BD - AD \cdot BD \\ AB \cdot CD &= AD \cdot CD + DB \cdot CD = AD \cdot CD - BD \cdot CD. \end{aligned}$$

It will be seen that the sum of the right hand sides vanishes, hence that

$$BC \cdot AD + CA \cdot BD + AB \cdot CD = 0 \quad \dots \dots (3)$$

for any four points on a line.

§ 11. If C is any point in the line AB, then we say that C divides the segment AB in the ratio $\frac{AC}{CB}$, account being taken of the sense of the two segments AC and CB. If C lies between A and B the ratio is positive, as AC and CB have the same sense. But if C lies without the segment AB, $\frac{AC}{CB}$, if C divides AB externally, then the ratio is negative. To see how the value of this ratio changes with C, we will move C along the whole line (fig. 3), whilst

Fig. 3.

A and B remain fixed. If C lies at the point A, then $AC = 0$, hence the ratio AC/CB vanishes. As C moves towards B, AC increases and CB decreases, so that our ratio increases. At the middle point M of AB it assumes the value $+1$, and then increases till it reaches an infinitely large value, when C arrives at B. On passing beyond B the ratio becomes negative. If C is at P we have $AC = AP = AB + BP$, hence

$$\frac{AC}{CB} = \frac{AB + BP}{BP} = \frac{AB}{BP} + 1.$$

In the last expression the ratio AB/BP is positive, has its greatest value ∞ when C coincides with B, and vanishes when B becomes infinite. Hence, as C moves from B to the right to the point at infinity, the ratio AC/CB varies from ∞ to $+1$.

If on the other hand C is to the left of A, say at Q, we have $AC = AQ = AB + BQ = AB - QB$, hence $\frac{AC}{CB} = \frac{AB}{CB} - 1$.

Here AB/CB , hence the ratio AB/CB is positive and always less than one, so that the whole is negative and < 1 . If C is at the point at infinity it is -1 , and then increases as C moves to the right, till for C at A we get the ratio $= 0$. Hence—

As C moves along the line from an infinite distance to the left to an infinite distance at the right, the ratio always increases; it starts with the value -1 , reaches 0 at A, $+1$ at B, changes now sign to ∞ , and increases till at an infinite distance it reaches again the value -1 . It assumes therefore all possible values from ∞ to $+\infty$, and each value only once, so that not only does every position of C determine a definite value of the ratio AC/CB , but also, conversely, to every positive or negative value of this ratio belongs one single point in the line AB.

PROJECTION AND CROSS-RATIO.

§ 12. If we join a point A to a point S, then the point where the line SA cuts a fixed plane π is called the projection of A on the plane π from S as centre of projection. If we have two planes π and π' and a point S, we may project every point A in π to the other plane. If A' is the projection of A, then A is also the projection of A', so that the relations are reciprocal. To every figure in π we get as its projection a corresponding figure in π' .

It will be our business to find such properties of figures as remain true for the projection, and which are called projective properties. For this purpose it will be sufficient to consider at first only constructions in one plane.

Let us suppose we have given in a plane two lines p and p' and a centre S (fig. 4); we may then project the points in p from S to p' . Let A, B, ... be the projections of A', B', ... the point at infinity in p which we shall denote by J will be projected into a finite point I' in p' , viz., into the point where the parallel to p through S cuts p' . Similarly one point J in p will be projected into the point I' at infinity in p' . This point J is of course the point where

Fig. 4.

the parallel to p' through S cuts p . We thus see that every point in p is projected into a single point in p' .

A glance at fig. 5 shows that a segment AB will be projected into a segment $A'B'$ which is not equal to it, at least not as a rule; and also that the ratio $AC:CB$ is not equal to the ratio $A'C':C'B'$ formed by the projections. These ratios will become equal only if p and p' are parallel, for in this case the triangle SAB is similar to the triangle $SA'B'$. Between three points in a line and their projections there exists therefore in general no relation. But between four points a relation does exist.

§ 13. Let A, B, C, D be four points in p, A', B', C', D' their projections in p' , then the ratio of the two ratios $AC:CB$ and $AD:DB$ into which C and D divide the segment AB is equal to the corresponding expression between A', B', C', D' . In symbols we have—

$$\frac{AC}{CB} \cdot \frac{AD}{DB} = \frac{A'C'}{C'B'} \cdot \frac{A'D'}{D'B'}$$

This is easily proved by aid of similar triangles.

Through the points A and B on p draw parallels to p' , which cut the projecting rays in C_2, D_2, B_2 and A_2, C_1, D_1 , as indicated in fig. 6. The two triangles AC_2C_1 and BD_2D_1 will be similar, as will also be the triangles ADD_2 and BDD_1 .

Fig. 5.

Fig. 6.

We have therefore—

$$\frac{AC}{CB} = \frac{AC_2}{C_2B} = \frac{AD_2}{D_2B} = \frac{AD_2}{D_1B} = \frac{AC_1}{A_2D_1} = \frac{C_1B}{D_1B};$$

where account is taken of the sense

Hence—

$$\frac{AC}{CB} \cdot \frac{AD}{DB} = \frac{AC_2}{C_2B} \cdot \frac{AD_2}{D_2B} = \frac{AC_1}{A_2D_1} \cdot \frac{C_1B}{D_1B};$$

but

$$\frac{AC_2}{A_2D_1} = \frac{A'C'}{A'D'} \quad \text{and} \quad \frac{C_1B}{D_1B} = \frac{C'B'}{D'B'};$$

so that the above expression becomes

$$\frac{A'C'}{A'D'} \cdot \frac{C'B'}{D'B'}$$

which is equal to $\frac{A'C'}{C'B'} \cdot \frac{A'D'}{D'B'}$ as required.

This result is of fundamental importance.

The expression formed has been called by Charles the anharmonic ratio of the four points A, B, C, D . Instead of this Professor Clifford has proposed the shorter and more expressive name of “cross-ratio.” We shall adopt the latter. We have then the

FUNDAMENTAL THEOREM.—The cross-ratio of four points in a line is equal to the cross-ratio of their projections on any other line which lies in the same plane with it.

§ 14. Before we draw conclusions from this result, we must investigate the meaning of a cross-ratio somewhat more fully.

If four points A, B, C, D are given, and we wish to form their cross-ratio, we have first to divide them into two groups of two, the points in each group being taken in a definite order. Thus, let A, B be the first, C, D the second pair, A and C being the first points in each pair. The cross-ratio is then the ratio $AC:CB$ divided by $AD:DB$. This will be denoted by $(ABCD)$, so that

$$(ABCD) = \frac{AC}{CB} \cdot \frac{AD}{DB}$$

This is easily remembered. In order to write it out, make first the two lines for the fractions, and put above and below these the letters A and B in their places, thus, $\frac{A}{B} : \frac{A}{B}$, and then fill up, crosswise, the first by C and the other by D .

§ 15. If we take the points in a different order, the value of the cross-ratio will change. We can do this in twenty-four different ways by forming all permutations of the letters. But of these twenty-four cross-ratios groups of four are equal, so that there are really only six different ones.

We have the following rules—

I. If in a cross-ratio the two groups be interchanged, its value remains unaltered.

$$(ABCD) = (CDAB).$$

II. If in a cross-ratio the two points belonging one of the two groups be interchanged, the cross-ratio changes into its reciprocal.

$$(ABCD) = \frac{1}{(ABDC)}$$

III. If in a cross-ratio the two middle letters be interchanged, the cross-ratio κ changes into its complement $1 - \kappa$.

$$(ABCD) = 1 - (ACBD)$$

The first two are easily proved by writing out their values. The third is proved by aid of the formula (3), § 10,

$$BC \cdot AD + CA \cdot BD + AB \cdot CD = 0.$$

If we divide this by $CB \cdot AD$ we get

$$-1 + \frac{CA}{CB} \cdot \frac{BD}{AD} + \frac{AB}{CB} \cdot \frac{CD}{AD} = 0,$$

or,

$$\frac{AC}{CB} \cdot \frac{AD}{DB} + \frac{AB}{CB} \cdot \frac{AD}{DB} = 1;$$

that is,

$$(ABCD) + (ACBD) = 1,$$

which was to be proved.

IV. From II it follows at once that if we interchange the elements in each pair, the cross-ratio remains unaltered; and thus we see that

$$\begin{aligned} (ABCD) &= (CDAB) && \text{by I.} \\ &= (BADC) = (DCBA) && \text{by II.} \end{aligned}$$

§ 16. By aid of these rules we get the following results:—

$$(ABCD) = (BADC) = (CDAB) = (DCBA) = \kappa.$$

$$(ABDC) = (BACD) = (CDBA) = (DCAB) = \frac{1}{\kappa}$$

$$(ACBD) = (BDAC) = (CADB) = (DBCA) = 1 - \kappa.$$

$$(ACDB) = (BDCA) = (CABD) = (DBAC) = \frac{1}{1 - \kappa}$$

$$(ADBC) = (BCAD) = (CBDA) = (DABC) = \frac{\kappa - 1}{\kappa},$$

$$(ADCB) = (BCDA) = (CBAD) = (DABC) = \frac{\kappa - 1}{\kappa - 1}.$$

In the theorem that the cross-ratio of four points equals that of the projections, the points have, of course, to be taken in the same order.

§ 17. If one of the points of which a cross-ratio is formed is the point at infinity in the line, the cross-ratio changes into a simple ratio. It is convenient to let the point at infinity occupy the last place in the symbolic expression for the cross-ratio. Thus if I is a point at infinity, we have

$$(ABCI) = \frac{AC}{CB},$$

because

$$AI:IB = -1.$$

Every common ratio of three points in a line may thus be expressed as a cross-ratio, by adding the point at infinity to the group of points.

§ 18. If the points have special positions, the cross-ratios κ may become equal. If the first two shall be equal, we get $\kappa = \frac{1}{\kappa}$, or $\kappa^2 = 1$, $\kappa = \pm 1$.

If we take $\kappa = +1$, we have $(ABCD) = 1$, or $\frac{AC}{CB} = \frac{AD}{DB}$; that is, the points C and D coincide, provided that A and B are different. This is too special a case to be of much interest.

If, however, we take $\kappa = -1$, so that $(ABCD) = -1$, we have $\frac{AC}{CB} = -\frac{AD}{DB}$. Hence C and D divide AB internally and externally in the same ratio.

The four points are in this case said to be harmonic points, and C and D are said to be harmonic conjugates with regard to A and B .

But we have also (CDAB) = -1, so that A and B are harmonic conjugates with regard to C and D.

The principal property of harmonic points, upon which almost all applications depend, is this, that their cross-ratio remains unaltered if we interchange the two points belonging to one pair, viz.,

$$(ABCD) = (ABDC) = (BACD)$$

For four harmonic points the six cross-ratios which are generally different become two and two equal:

$$k = -1, 1 - k = 2, \frac{k}{k-1} = \frac{1}{2}.$$

$$\frac{1}{k} = -1, \frac{1}{1-k} = \frac{1}{2}, \frac{k-1}{k} = 2.$$

Hence if we get four points whose cross-ratio is 2 or $\frac{1}{2}$, then they are harmonic, but not arranged so that conjugates are paired. If this is the case the cross-ratio = -1.

§ 19 If we equate any two of the above six values of the cross-ratios, we get either $k=1, 0, \infty$, or $k=-1, 2, \frac{1}{2}$, or else k becomes a root of the equation $k^2 - k + 1 = 0$, that is, an imaginary cube root of -1. In this case the six values become three and three equal, so that only two different values remain. This case, though important in the theory of cubic curves, is for our purposes of no interest, whilst harmonic points are all-important.

§ 20 From the definition of harmonic points, and by aid of § 11, the following properties are easily deduced.

If C and D are harmonic conjugates with regard to A and B, then one of them lies in the other without AB; it is impossible to move from A to B without passing either through C or through D, the one blocks the finite way, the other the way through infinity. This is expressed by saying A and B are "separated" by C and D.

For every position of C there will be one and only one point D which is its harmonic conjugate with regard to any point pair A, B.

If A and B are different points, and if C coincides with A or B, D does. But if A and B coincide, one of the points C or D, lying between them, coincides with them, and the other may be anywhere in the line. It follows that, "if of four harmonic conjugates two coincide, then a third coincides with them, and the fourth may be any point in the line."

If C is the middle point between A and B, then D is the point at infinity for AC CB = +1, hence AD : DB must be equal to -1. The harmonic conjugate of the point at infinity in a line with regard to two points A, B is the middle point of AB.

This important property gives a first example how metric properties are connected with projective ones.

§ 21 *Complete Quadrilateral*.—A figure formed by four lines in a plane is called a complete quadrilateral or, shorter, a four-side (fig. 7). The figure has six vertices, that is, points where the sides meet, and three diagonals AB, EF, GH, which join opposite vertices.

Similarly a figure formed by four points in a plane is called a four-point. It has six sides, which join the points, or vertices, and three diagonal points, where the sides meet.

Fig. 7.

The three diagonals of a four-side cut each other harmonically.

If we project the points E, F, K, D from H to AB, we get

$$(EFKD) = (ABCD),$$

and if we project them from G, we get

$$(EFKD) = (BACD);$$

so that

$$(ABCD) = (BACD),$$

that is, the cross-ratio (ABCD) is equal to its reciprocal, hence = -1, as the four points are all different. This gives the important theorem—

THEOREM.—In every four-side any diagonal is cut harmonically by the other two.

This allows the solution of the problem:—

PROBLEM.—To construct the harmonic conjugate D to a point C with regard to two given points A and B.

Solution.—Through A draw any two lines, and through C one cutting the former two in G and H. Join these points to B, cutting the former two lines in E and F. The point D where EF cuts AB will be the harmonic conjugate required.

This remarkable construction requires nothing but the drawing of lines, and is therefore independent of measurement. It follows, also, that all four-sides which have two vertices at A and B, and

one diagonal passing through C, will each have the third diagonal passing through D.

§ 22 The theory of cross-ratios may be extended from points in a row to lines in a flat pencil, and to planes in an axial pencil. We have seen (§ 13) that if the lines which join four points A, B, C, D to any point S be cut by any other line in A', B', C', D', then (ABCD) = (A'B'C'D'). In other words, four lines in a flat pencil are cut by every other line in four points whose cross-ratio is constant.

Definition.—By the cross-ratio of four rays in a flat pencil is meant the cross-ratio of the four points in which the rays are cut by any line. If a, b, c, d be the lines, then this cross-ratio is denoted by (abcd).

Definition.—By the cross-ratio of four planes in an axial pencil is understood the cross-ratio of the four points in which any line cuts the planes, or, what is the same thing, the cross-ratio of the four rays in which any plane cuts the four planes.

In order that this definition may have a meaning, it has to be proved that all lines cut in a pencil in points which have the same cross-ratio. This is seen at once for two intersecting lines, as their plane cuts the axial pencil in a flat pencil, which is itself cut by the two lines. The cross-ratio of the four points on one line is therefore equal to that on the other, and equal to that of the four rays in the flat pencil.

If two non-intersecting lines p and q cut the four planes in A, B, C, D and A', B', C', D', draw a line r to meet both p and q, and let this line cut the planes in A'', B'', C'', D''. Then (ABCD) = (A'B'C'D') = (A''B''C''D').

§ 23. We may now also extend the notion of harmonic elements, viz., —

Definition.—Four rays in a flat pencil and four planes in an axial pencil are said to be harmonic if their cross-ratio equals -1, that is, if they are cut by a line in four harmonic points.

Harmonic pencils are constructed by aid of the theorem in § 21, which may now be stated thus:—

In a four-side two sides are harmonic conjugates with regard to the diagonal through their intersection, and the line from this point to the point where the other diagonals meet. Or thus: In a four-point the lines joining one diagonal point to the other two are harmonic conjugates with regard to the sides passing through the first.

If we understand by a "median line" of a triangle a line which joins a vertex to the middle point of the opposite side, and by a "median line" of a parallelogram a line joining middle points of opposite sides, we get as special cases of the last theorem —

The diagonals and median lines of a parallelogram form an harmonic pencil; and

At a vertex of any triangle, the two sides, the median line, and the line parallel to the base form an harmonic pencil.

Taking the parallelogram a rectangle, or the triangle isosceles, we get:—

THEOREM.—Any two lines and the bisections of their angles form an harmonic pencil. Or —

In an harmonic pencil, if two conjugate rays are perpendicular, then the other two are equally inclined to them; and, conversely, if one ray bisects the angle between conjugate rays, it is perpendicular to its conjugate.

This connects perpendicularity and bisection of angles with projective properties.

§ 24. We add a few theorems and problems which are easily proved or solved by aid of harmonics.

An harmonic pencil is cut by a line parallel to one of its rays in three equidistant points.

Through a given point to draw a line such that the segment determined on it by a given angle is bisected at that point.

Having given two parallel lines, to bisect on either any given segment without using a pair of compasses.

Having given in a line a segment and its middle point, to draw through any given point in the plane a line parallel to the given line.

To draw a line which joins a given point to the intersection of two given lines which meet off the drawing paper (by aid of § 21).

CORRESPONDENCE.

§ 25 Two rows, p and p', which are one the projection of the other (as in fig. 5), stand in a definite relation to each other, characterized by the following properties.

1. To each point in either corresponds one point in the other; that is, these points are said to correspond which are projections of one another.

2. The cross-ratio of any four points in one equals that of the corresponding points in the other.

3. The lines joining corresponding points all pass through the same point.

If we suppose corresponding points marked, and the rows brought into any other position, then the lines joining corresponding points will no longer meet in a common point, and hence the third of the above properties will not hold any longer; but we have still a

correspondence between the points in the two rows possessing the first two properties. Such a correspondence has been called a *one-one correspondence*, whilst the two rows between which such correspondence has been established are said to be *projective* or *homologous*. Two rows which are each the projection of the other are therefore *projective*. We shall presently see, also, that any two projective rows may always be placed in such a position that one appears as the projection of the other. If they are in such a position the rows are said to be in *perspective position*, or simply to be *perspective*.

§ 26 The notion of a one-one correspondence between rows may be extended to flat and axial pencils, viz., a flat pencil will be said to be projective to a flat pencil if each ray in the first corresponds one ray in the second, and if the cross-ratio of four rays in one equals that of the corresponding rays in the second.

Similarly an axial pencil may be projective to an axial pencil. But a flat pencil may also be projective to an axial pencil, or either pencil may be projective to a row. The definition is the same in each case: there is a one-one correspondence between the elements, and four elements have the same cross-ratio as the corresponding ones.

§ 27 There is also in each case a special position which is called *perspective*, viz. —

1. Two projective rows are perspective if they lie in the same plane, and if the one row is a projection of the other.

2. Two projective flat pencils are perspective—(a) if they lie in the same plane, and have a row as a common section, (b) if they lie in the same pencil (in space), and are both sections of the same axial pencil, (c) if they are in space and have a row as common section, or are both sections of the same axial pencil, one of the conditions involving the other.

3. Two projective axial pencils, if their axes meet, and if they have a flat pencil as a common section.

4. A row and a projective flat pencil, if the row is a section of the pencil, each point lying in its corresponding line.

5. A row and a projective axial pencil, if the row is a section of the pencil, each point lying in its corresponding line.

6. A flat and a projective axial pencil, if the former is a section of the other, each ray lying in its corresponding plane.

That in each case the correspondence established by the position indicated is such as has been called projective follows at once from the definition. It is not so evident that the perspective position always be obtained. We shall show in § 30 this for the first three cases.

First, however, we shall give a few theorems which relate to the general correspondence, not to the perspective position.

§ 28. THEOREM.—Two rows or pencils, flat or axial, which are projective to a third are projective to each other, as follows at once from the definitions.

§ 29. FUNDAMENTAL THEOREM.—If two rows, or two pencils, either flat or axial, or a row and a pencil, shall be projective, we may assume to any three elements on the one the three corresponding elements in the other, and then the correspondence is uniquely determined.

Proof.—If in two projective rows we assume that the points A, B, C in the first correspond to the given points A', B', C' in the second, then to any fourth point D in the first will correspond a point D' in the second, so that

$$(ABCD) = (A'B'C'D')$$

But there is only one point, D' , which makes the cross-ratio $(A'B'C'D')$ equal to the given number $(ABCD)$.

The same reasoning holds in the other cases.

§ 30. THEOREM.—If two rows are perspective, then the lines joining corresponding points all meet in a point, the centre of projection; and the point in which the two bases of the rows intersect as a point in the first row coincides with its corresponding point in the second.

This follows from the definition. The converse also holds, viz. —

THEOREM.—If two projective rows have such a position that one point in the one coincides with its corresponding point in the other, then they are perspective, that is, the lines joining corresponding points all pass through a common point, and form a flat pencil.

Proof.—Let A, B, C, D, \dots be points in the one, and A', B', C', D', \dots the corresponding points in the other row, and let A be made to coincide with its corresponding point A' . Let S be the point where the lines BB' and CC' meet, and let us join S to the point D in the first row. This line will cut the second row in a point D' , so that A, B, C, D are projected from S into the points A', B', C', D' . The cross-ratio $(ABCD)$ is therefore equal to $(A'B'C'D')$, and by hypothesis it is equal to $(A'B'C'D)$. Hence $(A'B'C'D) = (A'B'C'D')$, that is, D' is the same point as D .

§ 31. THEOREM.—If two projected flat pencils in the same plane are perspective, then the intersections of corresponding lines form a row, and the line joining the two centres as a line in the first pencil corresponds to the same line as a line in the second. And conversely.

THEOREM.—If two projective pencils in the same plane, but with different centres, have one line in the one coincident with its corresponding line in the other, then the two pencils are perspective, that is, the intersection of corresponding lines lie in a line.

The proof is the same as in § 30.

§ 32. THEOREM.—If two projective flat pencils in the same point (pencil in space), but not in the same plane, are perspective, then the planes joining corresponding rays all pass through a line (they form an axial pencil), and the line common to the two pencils (in which their planes intersect) corresponds to itself. And conversely.

THEOREM.—If two flat pencils which have a common centre, but do not lie in a common plane, are placed so that one ray in the one coincides with its corresponding ray in the other, then they are perspective, that is, the planes joining corresponding lines all pass through a line.

§ 33. THEOREM.—If two projective axial pencils are perspective, then the intersection of corresponding planes lie in a plane, and the plane common to the two pencils (in which the two axes lie) corresponds to itself. And conversely.

THEOREM.—If two projective axial pencils are placed in such a position that a plane in the one coincides with its corresponding plane, then the two pencils are perspective, that is, corresponding planes meet in lines which lie in a plane.

The proof again is the same as in § 30.

§ 34. These theorems relating to perspective position become illusory if the projective rows of pencils have a common base. We then have—

THEOREM.—In two projective rows on the same line—and also in two projective and concentric flat pencils in the same plane, or in two projective axial pencils with a common axis—every element in the one coincides with its corresponding element in the other as soon as three elements in the one coincide with their corresponding elements in the other.

Proof (in case of two rows).—Between four elements A, B, C, D and their corresponding elements A', B', C', D' exists the relation $(ABCD) = (A'B'C'D')$. If now A, B, C coincide respectively with A', B', C' , we get $(ABCD) = (ABCD')$; hence D and D' coincide.

The last theorem may also be stated thus:—

THEOREM.—In two projective rows or pencils, which have a common base but are not identical, not more than two elements in the one can coincide with their corresponding elements in the other.

Thus two projective rows on the same line cannot have more than two pairs of coincident points unless every point coincides with its corresponding point.

It is easy to construct two projective rows on the same line, which have two pairs of corresponding points coincident. Let the points A, B, C as points belonging to the one row correspond to A', B', C' as points in the second.

Then A and B coincide with their corresponding points, but C does not. It is, however, not necessary that two such rows have twice a point coincident with its corresponding point; it is possible that this happens only once or not at all. Of this we shall see plenty of examples as we go on.

§ 35. If two projective rows or pencils

are in perspective position, we know at once which element in one corresponds to any given element in the other. If p and q (fig. 8)

are two projective rows, so that K corresponds to itself, and if we know that A and B in p correspond A' and B' in q , then the point S , where AA' meets BB' , is the centre of projection, and hence, in order to find the point C corresponding to C' , we have only to join C to S ; the point C , where this line cuts q , is the point required.

If two flat pencils, S_1 and S_2 , in a plane are perspective (fig. 9), we need only to know two pairs, a, a' and b, b' , of corresponding rays in order to find the axis of projection. This being known, a ray c' in S_2 corresponding

Fig. 8.

Fig. 9

to a given ray e in S_1 , is found by joining S_2 to the point where e cuts the axis s .

A similar construction holds in the other cases of perspective figures.

§ 36 *Problem*.—Three pairs of corresponding elements in two projective rows or pencils being given, to determine for any element in one the corresponding element in the other.

We solve this in the two cases of two projective rows and of two projective flat pencils in a plane.

Problem I.—Let A, B, C be three points in a row s , A', B', C' the corresponding points in a projective row s' , both being in a plane, it is required to find for any point D in s the corresponding point D' in s' .

Problem II.—Let a, b, c be three rays in a pencil S , a', b', c' the corresponding rays in a projective pencil S' , both being in the same plane, it is required to find for any ray d in S the corresponding ray d' in S' .

The solution is made to depend on the construction of an auxiliary row or pencil which is perspective to both the given ones. This is found as follows:—

Solution of Problem I.—On the line joining two corresponding points, say AA' (fig. 10), take any two points, S and S' , as centres of auxiliary pencils. Join the intersection B_1 of SB and $S'B'$ to the intersection C_1 of SC and $S'C'$ by the line s_1 . Then a row on s_1 will be perspective to s with S as centre of projection, and to s' with S' as centre. To find now the point D' on s' corresponding to a point D on s we have only to determine the point B_2 , where the line SD cuts s_1 , and to draw $S'D_2$; the point where this line cuts s' will be the required point D' .

Proof.—The rows s and s' are both perspective to the row s_1 , hence they are perspective to one another. To A, B, C, D on s correspond A_1, B_1, C_1, D_1 on s_1 , and to these correspond A', B', C', D' on s' , so that D and D' are corresponding points as required.

Solution of Problem II.—Through the intersection A of two corresponding rays a and a' (fig. 11), take two lines, s and s' , as bases of auxiliary rows. Let S be the point where the line b_1 , which joins B and B' , cuts the line c_1 , which joins C and C' . Then a pencil S will be perspective to s with s as axis of projection. To find the ray d' in S' corresponding to a given ray d in S , cut d by s at D ; project this point from S_1 to D' on s' and join D' to S' . This will be the required ray.

Proof.—That the pencil S_1 is perspective to s and also to s' follows from construction. To the lines a, b, c, d in S correspond the lines a, b, c, d in s and the lines a', b', c', d' in S' , so that d and d' are corresponding rays.

In the first solution the two centres, S, S' , are any two points on a line joining any two corresponding points, so that the solution of the problem allows of a great many different constructions. But whatever construction be used, the point D' , corresponding to D , must be always the same, according to the theorem in § 29. This gives rise to a number of theorems, into which, however, we shall not enter. The same remarks hold for the second problem.

§ 37. As a further application of the theorems about perspective rows and pencils we shall prove the following important theorem.

Theorem.—If ABC and $A'B'C'$ (fig. 12) be two triangles, such that the lines AA', BB', CC' meet in a point S , then the intersections of BC and $B'C'$, of CA and $C'A'$, and of AB and $A'B'$ will lie in a line.

Proof.—Let a, b, c denote the lines AA', BB', CC' , which meet at S . Then these may be taken as bases of projective rows, so that A, A', S on a correspond to B, B', S on b , and to C, C', S on c . As the point S is common to all, any two of these rows will be perspective.

If S_1 be the centre of projection of rows b and c ,
 S_2 " " " " " c and a ,
 S_3 " " " " " a and b ,

and if the line S_1S_2 cuts a in A_1 , and b in B_1 , and c in C_1 , then A_1, B_1 will be corresponding points in a and b , both corresponding to C_1 in c . But a and b are perspective, therefore the line A_1B_1 , that is S_1S_2 , joining corresponding points must pass through the centre of projection S_3 of a and b . In other words, S_1, S_2, S_3 lie in a line. This is Desargues's celebrated theorem if we state it thus:—

Theorem of Desargues.

—If each of two triangles has one vertex on each of three concurrent lines, then the intersections of corresponding sides lie in a line, those sides being called corresponding which are opposite to vertices on the same line.

The converse theorem holds also, viz.—

Theorem.—If the sides of one triangle meet those of another in three points which lie in a line, then the vertices lie on three lines which meet in a point.

The proof is almost the same as before.

§ 38 *Metrical relations between projective rows*.—Every row contains one point which is distinguished from all others, viz. the point at infinity. In two projective rows, to the point I at infinity in one corresponds a point I' in the other, and to the point J' at infinity in the second corresponds a point J in the first. The points I and J are in general finite. If now A and B are any two points in the one, A', B' the corresponding points in the other row, then

$$(ABJI) = (A'B'J'I')$$

Or,

$$\frac{AJ}{JB} \cdot \frac{AI}{IB} = \frac{A'I'}{I'B'} \cdot \frac{A'I'}{I'B'};$$

but, by § 17,

$$\frac{AI}{IB} = \frac{A'I'}{I'B'} = -1,$$

therefore the last equation changes into

$$\frac{AJ}{JB} \cdot \frac{A'I'}{I'B'} = 1,$$

or into

$$AJ \cdot A'I' = JB \cdot B'I',$$

that is to say—

Theorem.—The product of the distances of any two corresponding points in two projective rows from the points which correspond to the points at infinity in the other is constant, viz., $AJ \cdot A'I' = k$. Steiner has called this number k the *Power of the correspondence*.

§ 39 *Similar Lines*.—If the points at infinity in two projective rows correspond so that I and J are at infinity, this result loses its meaning. But if A, B, C be any three points in one A', B', C' the corresponding ones on the other row, we have

$$(ABCI) = (A'B'C'I'),$$

which reduces to

$$\frac{AC}{CB} = \frac{A'C'}{C'B'}; \text{ or } \frac{AC}{A'C'} = \frac{CB}{C'B'},$$

that is, corresponding segments are proportional. Conversely, if corresponding segments are proportional, then to the point at infinity in one corresponds the point at infinity in the other. If we call such rows *similar*, we may state the result thus—

Theorem.—Two projective rows are similar if to the point at infinity in one corresponds the point at infinity in the other, and conversely, if two rows are similar then they are projective, and the points at infinity are corresponding points.

From this the well-known propositions follow.—

Two lines are cut proportionally (in similar rows) by a series of parallels. The rows are perspective, with centre of projection at infinity.

If two similar rows are placed parallel, then the lines joining homologous points pass through a common point.

§ 40 *Theorem*.—If two flat pencils be projective, then there exists in either one single pair of lines at right angles to one another, such that the corresponding lines in the other pencil are again at right angles.

To prove this, we place the pencils in perspective position (fig. 13) by making one ray coincident with its corresponding ray. Corresponding rays meet then on a line p . And now we draw the circle which has its centre O on p , and which passes through the

Fig. 10.

Fig. 11.

Fig. 12.

centres S and S' of the two pencils. This circle cuts p in two points H and K . The two pairs of rays, h, k and h', k' , joining these points to S and S' will be pairs of corresponding rays at right angles. The construction gives in general but one circle, but if the line p is the perpendicular bisector of SS' , there exists an infinite number, and to every right angle in the one pencil corresponds a right angle in the other.

Fig. 13.

PRINCIPLE OF DUALITY.

§ 41. It has been stated in § 1 that not only points, but also planes and lines, are taken as elements out of which figures are built up. We shall now see that the construction of one figure which possesses certain properties gives rise in many cases to the construction of another figure, by replacing, according to definite rules, elements of one kind by those of another. The new figure thus obtained will then possess properties which may be stated as soon as those of the original figure are known.

We obtain thus a principle, known as the principle of *duality* or *reciprocity*, which enables us to construct in any figure not containing any measurement in its construction a *reciprocal* figure, as it is called, and to deduce from any theorem a *reciprocal* theorem, for which no further proof is needed.

It is convenient to print reciprocal propositions on opposite sides of a page broken into two columns, and thus plan will occasionally be adopted.

We begin by repeating in this form a few of our former statements:

Two points determine a line.	Two planes determine a line.
Three points which are not in a line determine a plane.	Three planes which do not pass through a line determine a point.
A line and a point without it determine a plane.	A line and a plane not through it determine a point.
Two lines in a plane determine a point.	Two lines through a point determine a plane.

These propositions show that it will be possible, when any figure is given, to construct a second figure by taking planes instead of points, and points instead of planes, but lines where we had lines.

For instance, if in the first figure we take a plane and three points in it, we have to take in the second figure a point and three planes through it. The three points in the first, together with the three lines joining them two and two, form a triangle; the three planes in the second and their three lines of intersection form a trihedral angle. A triangle and a trihedral angle are therefore reciprocal figures.

Similarly, to any figure in a plane consisting of points and lines will correspond a figure consisting of planes and lines passing through a point S , and hence belonging to the pencil which has S as centre. The figure reciprocal to four points in space which do not lie in a plane will consist of four planes which do not meet in a point. In this case each figure forms a tetrahedron.

§ 42. As other examples we have the following:—

To a row	is reciprocal an axial pencil,
„ a flat pencil	„ a flat pencil,
„ a field of points and lines	„ a pencil of planes and lines,
„ the space of points	„ the space of planes

For the row consists of a line and all the points in it, reciprocal to it therefore will be a line with all planes through it, that is, an axial pencil, and so for the other cases.

This correspondence of reciprocity breaks down, however, if we take figures which contain measurement in their construction. For instance, there is no figure reciprocal to two planes at right angles, because there is no segment in a row which has a magnitude as definite as a right angle.

We add a few examples of reciprocal propositions which are easily proved

Theorem.—If A, B, C are any four points in space, and if the lines AB and CD meet, then all four points lie in a plane, hence also AC and BD , as well as AD and BC , meet.

Theorem.—If $\alpha, \beta, \gamma, \delta$ are four planes in space, and if the lines $\alpha\beta$ and $\gamma\delta$ meet, then all four planes lie in a point (pencil), hence also $\alpha\gamma$ and $\beta\delta$, as well as $\alpha\delta$ and $\beta\gamma$, meet.

Theorem.—If of any number of lines every one meets every other, whilst all do not

lie in a point, then all lie in a plane

lie in a plane, then all lie in a point (pencil).

§ 43. Reciprocal figures as explained lie both in space of three dimensions. If the one is confined to a plane (is formed of elements which lie in a plane), then the reciprocal figure is confined

But there is also a more special principle of duality, according to which figures are reciprocal which lie both in a plane or both in a pencil. In the plane we take points and lines as reciprocal elements, for they have this fundamental property in common, that two elements of one kind determine one of the other. In the pencil, on the other hand, lines and planes have to be taken as reciprocal, and here it holds again that two lines or planes determine one plane or line.

Thus, to one plane figure we can construct one reciprocal figure in the plane, and to each one reciprocal figure in a pencil. We mention a few of these. At first we explain a few names:—

A figure consisting of n points in a plane will be called an n -point	A figure consisting of n lines in a plane will be called an n -side
A figure consisting of n planes in a pencil will be called an n -flat	A figure consisting of n lines in a pencil will be called an n -edge

It will be understood that an n -side is different from a polygon of n sides. The latter has sides of finite length and n vertices, the former has sides all of infinite extension, and every point where two of the sides meet will be a vertex. A similar difference exists between a solid angle and an n -edge or an n -flat. We notice particularly—

A four-point has six sides, of which two and two are opposite, and three diagonal points, which are intersections of opposite sides.

A four-flat has six edges, of which two and two are opposite, and three diagonal planes, which pass through opposite edges.

A four-side is usually called a complete quadrilateral. This above notation, however, seems better adapted for the statement of reciprocal propositions.

§ 44.

If a point moves in a plane it describes a plane curve.

If a plane moves in a pencil it envelopes a cone

If a line moves in a plane it envelopes a plane curve (fig. 14).

If a line moves in a pencil it describes a cone

A curve thus appears as generated either by points, and then we call it a “locus,” or by lines, and then we call it an “envelope.” In the same manner a cone, which means here a surface, appears either as the locus of lines passing through a fixed point, the vertex of the cone, or as the envelope of planes passing through the same point.

To a surface as locus of points corresponds, in the same manner, a surface as envelope of planes; and to a curve in space as locus of points corresponds a developable surface as envelope of planes. Of the latter we shall not say any more at present.

It will be seen from the above that we may, by aid of the principle of duality, construct for every figure a reciprocal figure, and that to any property of the one a reciprocal property of the other will exist, as long as we consider only properties which depend upon nothing but the positions and intersections of the different elements and not upon measurement.

For such propositions it will therefore be unnecessary to prove more than one of two reciprocal theorems.

CURVES AND CONES OF SECOND ORDER OR SECOND CLASS.

§ 45. If we have two projective pencils in a plane, corresponding rays will meet, and their point of intersection will constitute some locus which we have to investigate. Reciprocally, if two projective rows in a plane are given, then the lines which join corresponding points will envelope some curve. We prove first:—

Theorem.—If two projective flat pencils lie in a plane, but are neither perspective nor concurrent, then the locus of intersections of corresponding rays is a curve of the second order, that is, no line contains more than two points of the locus.

Proof.—We draw any line t . This cuts each of the pencils in a row, so that we have on two rows, and these are projective because the pencils are projective. If corresponding rays of the two pencils meet on the line t , their intersection will be a point in the one row which coincides with its corresponding point in the other. But two projective rows on the same base cannot have more than two points of one coincident with their corresponding points in the other (§ 34).

It will be seen that the proofs are reciprocal, so that the one may be copied from the other by simply interchanging the words point and line, locus and envelope, row and pencil, and so on. We shall

Fig. 14.

theorems, and often state one theorem only, the reader being recommended to go through the reciprocal proof by himself, and to supply the reciprocal theorems when not given.

§ 46. We state the theorems in the pencil reciprocal to the last, without proving them —

Theorem.—If two projective flat pencils are concentric, but are neither perspective nor co-planar, then the envelope of the planes joining corresponding rays is a cone of the second class, that is, no line through the common centre cuts it more than twice of the enveloping planes.

§ 47. Of theorems about cones of second order and cones of second class we shall state only very few. We point out, however, the following connexion between the curves and cones under consideration. —

The lines which join any point in space to the points on a curve of the second order form a cone of the second order.

The planes which join any point in space to the lines enveloping a curve of the second class envelope themselves a cone of the second class.

By its aid, or by the principle of duality, it will be easy to obtain theorems about them from the theorems about the curves.

We prove the first. A curve of the second order is generated by two projective pencils. These pencils, when joined to the point in space, give rise to two projective axial pencils, which generate the cone in question as locus of the lines where corresponding planes meet.

§ 48

Theorem.—The curve of second order which is generated by two projective flat pencils passes through the centres of the two pencils.

Proof.—If S and S' are the two pencils, then to the ray SS' or p' in the pencil S' corresponds in the pencil S a ray p , which is different from p' , for the pencils are not perspective. But p and p' meet at S , so that S is a point on the curve, and similarly S' .

It follows that every line in one of the two pencils cuts the curve in two points, viz., once at the centre S of the pencil, and once where it cuts its corresponding ray in the other pencil. These two points, however, coincide, if the line is cut by its corresponding line at S itself. The line p in S , which corresponds to the line SS' in S' , is therefore the only line through S which has but one point in common with the curve, or which cuts the curve in two coincident points. Such a line is called a tangent to the curve, touching the latter at the point S , which is called the point of contact.

In the same manner we get in the reciprocal investigation the result that through every point in one of the rows, say in s , two tangents may be drawn to the curve, the one being s , the other the line joining the point to its corresponding point in s' . There is, however, one point P in s for which these two lines coincide. Such a point in one of the tangents is called the "point of contact" of the tangent. We thus get—

Theorem.—To the line joining the centres of the projective pencils as a line in one pencil corresponds in the other the tangent at its centre.

§ 49. Two projective pencils are determined if three pairs of corresponding lines are given. Hence if a_1, b_1, c_1 are three lines in a pencil S_1 , and a_2, b_2, c_2 the corresponding lines in a projective pencil S_2 , the correspondence and therefore the curve of the second order generated by the points of intersection of corresponding rays is determined. Of this curve we know the two centres S_1 and S_2 , and the three points a_1a_2, b_1b_2, c_1c_2 , hence five points in all. This and the reciprocal considerations enable us to solve the following two problems:—

Problem.—To construct a curve of the second order, of which five points S_1, S_2, A, B, C are given.

In order to solve the left-hand problem, we take two of the given points, say S_1 and S_2 , as centres of pencils. These we make projective by taking the rays a_1, b_1, c_1 , which join S_1 to A, B, C respectively, as corresponding to the rays a_2, b_2, c_2 , which join S_2 to A, B, C respectively, so that three rays meet their corresponding rays at the given points A, B, C . This determines the correspondence of the pencils which will generate a curve of the second order passing through A, B, C and through the centres S_1 and S_2 , hence through the five given points. To find more points on the curve we have to construct for any ray in S_1 the corresponding ray in S_2 . This has been done in § 36. But we repeat the con-

struction in order to deduce further properties from it. We also solve the right-hand problem. Here we select two, viz., u_1, u_2 of the five given lines, u_1, u_2, a, b, c , as bases of two rows, and the points A_1, B_1, C_1 where a, b, c cut u_1 as corresponding to the points A_2, B_2, C_2 where a, b, c cut u_2 .

Fig. 15.

We get then the following solutions of the two problems:—

Solution.—Through the point A draw any two lines, u_1 and u_2 (fig. 15), the first u_1 to cut the pencil S_1 in a row $A_1B_1C_1$, the other u_2 to cut the pencil S_2 in a row $A_2B_2C_2$. These two rows will be perspective, as the point A corresponds to itself, and the centre of projection will be the point S , where the lines B_1B_2 and C_1C_2 meet. To find now for any ray d_1 in S_1 its corresponding ray d_2 in S_2 , we determine the point D , where d_1 cuts u_1 , project this point from S_1 to D_1 on u_2 , and join S_2 to D_1 . This will be the required ray d_2 which cuts d_1 at some point D on the curve.

Solution.—In the line a take any two points S_1 and S_2 as centres of pencils (fig. 15), the first $S_1(A_1B_1C_1)$ to project the row u_1 , the other $S_2(A_2B_2C_2)$ to project the row u_2 . These two pencils will be perspective, the line S_1A_1 being the same as the corresponding line S_2A_2 , and the axis of projection will be the line u_1 , which joins the intersection B of S_1B_1 and S_2B_2 to the intersection C of S_1C_1 and S_2C_2 . To find now for any point D_1 on u_1 the corresponding point D_2 on u_2 , we draw S_1D_1 and project the point D where this line cuts u_2 from S_2 to u_2 . This will give the required point D_2 , and the line d_1 joining D_1 to D_2 will be a new tangent to the curve.

Fig. 16.

§ 50. These constructions prove, when rightly interpreted, very important properties of the curves in question.

If in fig. 15 we draw in the pencil S_1 the ray k_1 , which passes through the auxiliary centre S_2 , it will be found that the corresponding ray k_2 cuts it on u_2 . Hence—

Theorem.—In the above construction the locus of the auxiliary rows u_1 and u_2 cut the curve where they cut the rays S_1S_2 and S_2S_1 respectively.

As A is any given point on the curve, and u_1 any line through it, we have solved the problems:—

Problem.—To find the second point in which any line through a known point on the curve cuts the curve.

As we determine in S_1 (fig. 15) the ray corresponding to the ray S_2S_1 in S_2 , we get the tangent at S_1 . Similarly we can determine the point of contact of the tangents u_1 or u_2 in fig. 16.

§ 51. If five points are given of which not three are in a line, then we can, as has just been shown, always draw a curve of the second order through them, we select two of the points as centres of projective pencils, and then one such curve is determined. It will be presently shown that we get always the same curve if two other points are taken as centres of pencils, that therefore five points deter-

name one curve of the second order, and reciprocally, that five tangents determine one curve of the second class. Six points taken at random will therefore not lie on a curve of the second order. In order that this may be the case a certain condition has to be satisfied, and this condition is easily obtained from the construction in § 49, fig. 15. If we consider the conic determined by the five points A, S_1, S_2, S_3, S_4 , then the point D will be on the curve if, and only if, the points on D_1, S, D_2 be in a line.

This may be stated differently if we take AKS, DS, L (figs. 15 and 17) as a hexagon inscribed in the conic, then AK and DS will be opposite sides, so will be KS and S_1L , as well as S_2D and LA . The first two meet in D_2 , the others in S and D , respectively. We may therefore state the required condition, together with the reciprocal one, as follows—

Pascal's Theorem.—If a hexagon be inscribed in a curve of the second order, the three intersections of opposite sides are three points in a line.

Branchon's Theorem.—If a hexagon be circumscribed about a curve of the second class, then the lines joining opposite vertices are three lines meeting in a point.

These celebrated theorems, which are known by the names of those discoverers, are perhaps the most fruitful in the whole theory of conics. Before we go over to their applications we have to show that we obtain the same curve if we take, instead of S_1, S_2 , any two other points on the curve as centres of projective pencils.

§ 52. We know that the curve depends only upon the correspondence between the pencils S_1 and S_2 , and not upon the special construction used for finding new points on the curve. The point A (fig. 15 or fig. 17), through which the two auxiliary rows u_1, u_2 were drawn, may therefore be changed to any other point on the curve. Let us now suppose the curve drawn, and keep the points S_1, S_2, K, L , and D , and hence also the point S fixed, whilst we move A along the curve. Then the line AL will describe a pencil about L as centre, and the point D , a row on S_2D perspective to the pencil L . At the same time AK describes a pencil about K and D , a row perspective to it on S_1D . But by Pascal's Theorem D_1 and D_2 will always lie in a line with S , so that the rows described by D_1 and D_2 are perspective. It follows that the pencils K and L will themselves be projective, corresponding rays meeting on the curve. This proves that we get the same curve whatever pair of the five given points we take as centres of projective pencils. Hence—

Theorem.—Only one curve of the second order can be drawn which passes through five given points.

Theorem.—Only one curve of the second class can be drawn which touches five given lines.

We have seen that if on a curve of the second order two points coincide at A , the line joining them becomes the tangent at A . If, therefore, a point on the curve and its tangent are given, this will be equivalent to having given two points on the curve. Similarly, if on the curve of second class a tangent and its point of contact are given, this will be equivalent to two given tangents.

We may therefore extend the last theorem—

Theorem.—Only one curve of the second order can be drawn, of which four points and one tangent are given, or three points and two tangents at two of them, are given.

Theorem.—Only one curve of the second class can be drawn, of which four tangents and one point of contact at one of them, or three tangents and the points of contact at two of them, are given.

§ 53. At the same time it has been proved—

Theorem.—If all points on a curve of the second order be joined to any two of them, then the two pencils thus formed are projective, these rays being corresponding which meet on the curve. Hence—

The cross-ratio of four rays joining a point S on a curve of second order to four fixed points A, B, C, D in the curve is independent of the position of S , and is called the cross-ratio of the four points A, B, C, D .

If this cross-ratio is -1 , the four points are said to be four harmonic points.

We have seen that a curve of second order, as generated by projective pencils, has at the centre of each pencil one tangent; and further, that any point on the curve may be taken as centre of such pencil. Hence—

Theorem.—A curve of second order has at every point one tangent.

§ 54. We return to Pascal's and Branchon's theorems and their applications, and shall, as before, state the results both for curves of the second order and curves of the second class, but prove them only for the former.

Theorem.—A curve of second class has in every tangent a point of contact.

Theorem.—If a triangle is inscribed in a curve of second order, the points in which the sides are cut by the tangents at the opposite vertices meet in a point.

Pascal's theorem may be used when five points are given to find more points on the curve, viz., it enables us to find the point where any line through one of the given points cuts the curve again. It is convenient, in making use of Pascal's theorem, to number the points, to indicate the order in which they are to be taken in forming a hexagon, which, by the way, may be done in 60 different ways. It will be seen that 1 2 and (leaving out 3) 4 5 are opposite sides, so are 2 3 and (leaving out 4) 5 6, and also 3 4 and (leaving out 5) 6 1.

If the points 1 2 3 4 5 are given, and we want a 6th point on a line drawn through 1, we know all the sides of the hexagon with the exception of 5 6, and thus is found by Pascal's theorem.

If this line should happen to pass through 1, then 6 and 1 coincide, or the line 6 1 is the tangent at 1. And always if two consecutive vertices of the hexagon approach nearer and nearer, then the side joining them will ultimately become a tangent.

We may therefore consider a pentagon inscribed in a curve of second order and the tangent at one of its vertices as a hexagon, and thus get the theorem—

Theorem.—Every pentagon inscribed in a curve of second order has the property that the intersections of two pairs of non-consecutive sides lie in a line with the point where the fifth side cuts the tangent at the opposite vertex.

Theorem.—Every pentagon circumscribed about a curve of the second class has the property that the lines which join two pairs of non-consecutive vertices meet on that line which joins the fifth vertex to the point of contact of the opposite sides.

This enables us also to solve the following problems.
Problem.—Given five points on a curve of second order to construct the tangent at any one of them.

Problem.—Given five tangents to a curve of second class to construct the point of contact of any one of them.

Fig. 18

If twice two adjacent vertices coincide, the hexagon becomes a quadrilateral, with tangents at two vertices. These we take to be opposite, and get the following theorems—

Theorem.—If a quadrilateral be inscribed in a curve of second order, the intersections of opposite sides, and also the intersections of the tangents at opposite vertices, lie in a line (fig. 19).

Theorem.—If a quadrilateral be circumscribed about a curve of second class, the lines joining opposite vertices, and also the lines joining points of contact of opposite sides, meet in a point.

Fig. 19.

If we consider the hexagon made up of a triangle and the tangents at its vertices, we get—

Theorem.—If a triangle be inscribed in a curve of second order, the points in which the sides are cut by the tangents at the opposite vertices meet in a point.

Theorem.—If a triangle be circumscribed about a curve of second class, the lines which join the vertices to the points of contact of the opposite sides meet in a point (fig. 19).

§ 55. Of these theorems, those about the quadrilateral gave rise to a number of others. Four points A, B, C, D may in three different ways be formed into a quadrilateral, for we may take them in the order $ABCD$, or $ACBD$, or $ACDB$, so that either of the points B, C, D may be taken as the vertex opposite to A . Accordingly we may apply the theorem in three different ways.

Let A, B, C, D be four points on a curve of second order (fig. 20), and let us take them as forming a quadrilateral by taking the

Fig. 20.

points in the order $ABCD$, so that A, C and also B, D are pairs of opposite vertices. Then P, Q will be the points where opposite sides meet, and E, F the intersections of tangents at opposite vertices. The four points P, Q, E, F lie therefore in a line. The quadrilateral $ACBD$ gives us in the same way the four points Q, B, G, H in a line, and the quadrilateral $ABDC$ a line containing the four points R, P, I, K . These three lines form a triangle PQR .

The relation between the points and lines in this figure may be expressed more clearly if we consider $ABCD$ as a four-point inscribed in a conic, and the tangent at these points as a four-side circumscribed about it,—viz., it will be seen that P, Q, R are the diagonal points of the four-point $ABCD$, whilst the sides of the triangle PQR are the diagonals of the circumscribing four-side. Hence the theorem—

THEOREM.—Any four-point on a curve of the second order and the four-side formed by the tangents at these points stand in this relation that the diagonal points of the four-point lie in the diagonals of the four-side. And conversely,

If a four-point and a circumscribed four-side stand in the above relation, then a curve of the second order may be described which passes through the four points and touches there the four sides of these figures.

That the last part of the theorem is true follows from the fact that the four points A, B, C, D and the line a , as tangent at A , determine a curve of the second order, and the tangents to this curve at the other points B, C, D are given by the construction which leads to fig. 20.

The theorem reciprocal to the last is—

THEOREM.—Any four-side circumscribed about a curve of second class and the four-point formed by the points of contact stand in this relation that the diagonals of the four-side pass through the diagonal points of the four-point. And conversely,

If a four-side and an inscribed four-point stand in the above relation, then a curve of the second class may be described which touches the sides of the four-side at the points of the four-point.

§ 56. The four-point and the four-side in the two reciprocal theorems are alike. Hence if we have a four-point $ABCD$ and a four-side $abcd$ related in the manner described, then not only may a curve of the second order be drawn, but also a curve of the second class, which both touch the lines a, b, c, d at the points A, B, C, D .

The curve of second order is already more than determined by the points A, B, C and the tangents a, b, c at A, B, C . The point D may therefore be any point on this curve, and d any tangent to the curve. On the other hand the curve of the second class is more than determined by the three tangents a, b, c and their points of contact A, B, C , so that d is any tangent to this curve. It follows that every tangent to the curve of second order is a tangent of a curve of the second class having the same point of contact. In other words, the curve of second order is a curve of second class, and vice versa. Hence the important theorems—

THEOREM.—Every curve of second order is a curve of second class. **THEOREM.**—Every curve of second class is a curve of second order.

The curves of second order and of second class having thus been proved to be identical shall henceforth be called by the common name of *Conics*.

For these curves hold, therefore, all properties which have been proved for curves of second order or of second class. We may therefore now state Pascal's and Brianchon's theorem thus—

Pascal's Theorem.—If a hexagon be inscribed in a conic, then the intersections of opposite sides lie in a line.

Brianchon's Theorem.—If a hexagon be circumscribed about a conic, then the diagonals forming opposite centres meet in a point.

§ 57. If we suppose in fig. 20 that the point D together with the tangent d moves along the curve, whilst A, B, C and their tangents a, b, c remain fixed, then the ray DA will describe a pencil about A , the point Q a projective row on the fixed line BC ; the point F the row b , and the ray EF a pencil about E . But EF passes always through Q . Hence the pencil described by AD is projective to the pencil described by EF , and therefore to the row described by F on b . At the same time the line BD describes a pencil about B projective to that described by AD (§ 53). Therefore the pencil BD and the row F on b are projective. Hence—

THEOREM.—If on a conic a point d be taken and the tangent a at this point then the cross-ratio of the four rays which join d to any four points on the curve is equal to the cross-ratio of the points in which the tangents at these points cut the tangent at d .

§ 58. There are theorems about conics of second order and second class in a pencil which are reciprocal to the above, according to § 43. We mention only a few of the more important ones.

Theorem.—The locus of intersections of corresponding planes in two projective axial pencils whose axes meet is a conic of the second order.

Theorem.—The envelope of planes which join corresponding lines in two projective axial pencils, not in the same plane, is a conic of the second class.

Theorem.—Conics of second order and conics of second class are identical.

Theorem.—Every plane cuts a conic of the second order in a conic.

THEOREM.—A conic of second order is uniquely determined by five of its edges or by five of its tangent pencils, or by four edges and the tangent pencil of one of them, &c.

Theorem (Pascal's).—If a solid angle of six faces be inscribed in a conic of the second order, then the intersections of opposite faces are three lines in a plane.

Theorem (Brianchon's).—If a solid angle of six edges be circumscribed about a conic of the second order, then the planes through opposite edges meet in a line.

Each of the other theorems about conics may be stated for conics of the second order.

§ 59. We have not yet considered the shape of the conics. We know that any line in the plane of the conic, and hence that the line at infinity, either has no point in common with the curve, or one (counting for two coincident points), or two distinct points. If the line at infinity has no point on the curve the latter is altogether finite, and is called an *Ellipse* (fig. 20). If the line at infinity has only one point in common with the conic, the latter extends to infinity, and has the line at infinity a tangent. It is called a *Parabola* (fig. 21). If, lastly, the line at infinity cuts the curve in two points, it consists of two separate parts which each extend to two branches to the points at infinity where they meet. The curve is in this case called an *Hyperbola* (see fig. 19, 24, or 25). The tangents at the two points at infinity are finite because the line at infinity is not a tangent. They are called *Asymptotes*. The branches of the hyperbola approach these lines indefinitely as a point on the curves moves to infinity.

§ 60. That the circle belongs to the curves of the second order is seen at once if we state in a slightly different form the theorem

that in a circle all angles at the circumference standing upon the same arc are equal. If two points S_1, S_2 on a circle be equal to any other two points A and B on the circle, then the angle included by the rays S_1A and S_2B is equal to that between the rays S_1A and S_2B , so that as A moves along the circumference the rays S_1A and S_2A describe equal and therefore projective pencils. The circle can thus be generated by two projective pencils, and is a curve of the second order.

If we join a point in space to all points on a circle, we get a (circular) cone of the second order (§ 43). Every plane section of this cone is a conic. This cone will be an ellipse, a parabola, or an hyperbola, according as the line at infinity in the plane has no, one, or two points in common with the conic in which the plane at infinity cuts the cone. It follows that our curves of second order may be obtained as sections of a circular cone, and that they are identical with the "Conic Sections" of the Greek mathematicians.

§ 61 Any two tangents to a parabola are cut by all others in projective rows; but the line at infinity being one of the tangents, the points at infinity on the rows are corresponding points, and the rows therefore similar. Hence—

THEOREM.—*The tangents to a parabola cut each other proportionally.*

POLE AND POLAR.

§ 62 We return once again to the remarkable figure (fig 20) which we obtained in § 55

If a four-side be circumscribed about and a four-point inscribed in a conic, so that the vertices of the second are the points of contact of the sides of the first, then the triangle formed by the diagonals of the first is the same as that formed by the diagonal points of the other.

Such a triangle will be called a *polar triangle* of the conic, so that PQR in fig. 20 is a polar triangle. It has the property that on the side p opposite P meet the tangents at A and B , and also those at C and D . From the harmonic properties of four-points and four-sides it follows further that the points L, M , where it cuts the lines AB and CD , are harmonic conjugates with regard to AB and CD respectively.

If the point P is given, and we draw a line through it, cutting the conic in A and B , then the point Q harmonic conjugate to P with regard to AB , and the point H where the tangents at A and B meet, are determined. But they lie both on p , and therefore this line is determined. If we now draw a second line through P , cutting the conic in C and D , then the point M harmonic conjugate to P with regard to CD , and the point G where the tangents at C and D meet, must also lie on p . As the first line through P already determines p , the second may be any line through P . Now every two lines through P determine a four-point $ABCD$ on the conic, and therefore a polar-triangle which has one vertex at P and its opposite side at p . This result, together with its reciprocal, give the theorem:—

THEOREM.—*All polar-triangles which have one vertex in common have also the opposite side in common.*

All polar-triangles which have one side in common have also the opposite vertex in common.

§ 63 To any point P in the plane of but not on a conic corresponds thus one line p as the side opposite to P in all polar triangles which have one vertex at P , and reciprocally to every line p corresponds one point P as the vertex opposite to p in all triangles which have p as one side.

We call the line p the *polar* of P , and the point P the *pole* of the line p with regard to the conic.

If a point lies on the conic, we call the tangent at that point its polar; and reciprocally we call the point of contact the pole of tangent.

§ 64 From these definitions and former results follow—

THEOREM.—*The polar of any point P not on the conic is a line p , which has the following properties:—*

THEOREM.—*The pole of any line p not a tangent to the conic is a point P , which has the following properties:—*

1. On every line through P which cuts the conic, it contains the harmonic conjugate of P with regard to those points on the conic.

2. If tangents can be drawn from P , their points of contact lie on p .

3. Tangents drawn at the points where any line through P cuts the conic, meet on p , and conversely.

4. If from any point on p tangents be drawn, their points of contact will lie in a line with P .

5. Any four-point on the conic which has one diagonal point at P has the other two lying on p .

The truth of 2 follows from 1. If T be a point where p cuts the conic, then one of the points where PT cuts the conic, and which are harmonic conjugates with regard to PT , coincides with T ; hence the other does—that is, PT touches the curve at T .

That 4 is true follows thus: If we draw from a point H on the polar one tangent a to the conic, join its point of contact A to the pole P , determine the second point of intersection B of this line with the conic, and draw the tangent at B , it will pass through H , and will therefore be the second tangent which may be drawn from H to the curve.

§ 65 The second property of the polar or pole gives rise to the theorem—

THEOREM.—*From a point in the plane of a conic, two, one, or no tangents may be drawn to the conic, according as its polar has two, one, or no points in common with the curve.*

1. Of all lines through a point on p from which two tangents may be drawn to the conic, it contains the line which is harmonic conjugate to p with regard to the two tangents.

2. If p cuts the conic, the tangents at the intersections meet at P .

3. The point of contact of tangents drawn from any point on p to the conic lie in a line with P , and conversely.

4. Tangents drawn at points where any line through P cuts the conic meet on p .

5. Any four-side circumscribed about a conic which has one diagonal point on p has the other two meeting at P .

Of any point in the plane of a conic we say that it was *without*, *on*, or *within* the curve according as two, one, or no tangents to the curve pass through it. The points on the conic separates those within the conic from those without. That this is true for a circle is known from elementary geometry. That it also holds for other conics follows from the fact that every conic may be considered as the projection of a circle, which will be proved later on.

The fifth property of pole and polar stated in § 64 shows how to find the polar of any point and the pole of any line by aid of the straight-edge only. Precisely it is often convenient to draw three secants through the pole and to determine only one of the diagonal points for two of the four-points formed by pairs of these lines and the conic (fig. 21).

These constructions also solve the problem —

PROBLEM.—*From a point without a conic, to draw the two tangents to the conic by aid of the straight-edge only.*

For we need only draw the polar of the point in order to find the points of contact.

§ 66 The property of a polar-triangle may now be stated thus—

THEOREM.—*In a polar-triangle each side is the polar of the opposite vertex, and each vertex is the pole of the opposite side.*

If P is one vertex of a polar-triangle, then the other vertices, Q and R , lie on the polar p of P . One of these vertices we may choose arbitrarily. For from any point Q on the polar a secant be drawn cutting the conic in A and D (fig. 22), and if the lines joining these points to P cut the conic again at B and C , then the line BC will pass through Q . Hence P and Q are two of the vertices on the polar-triangle which is determined by the four-point $ABCD$. The third vertex R lies also on the line p . It follows, therefore, also—

THEOREM.—*If Q is a point on the polar of P , then P is a point on the polar of Q ; and reciprocally.*

If q is a line through the pole of p , then p is a line through the pole of q .

This is a very important theorem. It may also be stated thus—
THEOREM.—*If a point moves along a line describing a row, its polar turns about the pole of the line describing a pencil.*

This pencil is projective to the row, so that the cross-ratio of four poles in a row equals the cross-ratio of its four polars, which pass through the pole of the row.

To prove the last part, let us suppose that P, A , and B in fig. 22 remain fixed, whilst Q moves along the polar p of P . This will

Fig. 21.

Fig. 22.

make CD turn about P and move R along p, whilst QD and RD describe projective pencils about A and B. Hence Q and R describe projective rows, and hence PR, which is the polar of Q, describes a pencil projective to either.

§ 67. Two points, of which one, and therefore each, lies on the polar of the other, are said to be *conjugate with regard to the conic*, and two lines, of which one, and therefore each, passes through the pole of the other, are said to be *conjugate with regard to the conic*. Hence all points conjugate to a point P lie on the polar of P, all lines conjugate to a line p pass through the pole of p.

If the line joining two conjugate poles cuts the conic, then the poles are harmonic conjugates with regard to the points of intersection; hence one lies within the conic without the conic, and all points conjugate to a point within the conic lie without it.

Of a polar-triangle having two vertices are conjugate poles, any two sides conjugate lines. If, therefore, one side cuts a conic, then one of the two vertices which lie on this side is within and the other without the conic. The vertex opposite this side lies also without, for it is the pole of a line which cuts the curve. In this case therefore one vertex lies within, the other two without. If, on the other hand, we begin with a side which does not cut the conic, then its pole lies within and the other vertices without. Hence—
Theorem.—Every polar triangle has one and only one vertex within the conic.

We add, without a proof, the theorem—

Theorem.—The four points in which a conic is cut by two conjugate polars are four harmonic points on the conic.

§ 68. If two conics intersect in four points (they cannot have more points in common, § 59), there exists one and only one four-point which is inscribed in both, and therefore one polar triangle common to both.

Theorem.—Two conics which intersect in four points have always one and only one common polar-triangle, and reciprocally.

Two conics which have four common tangents have always one and only one common polar-triangle.

The proof that these polar triangles are identical in case of a conic which have four points and also four tangents in common is left to the reader.

DIAMETERS AND AXES OF CONICS.

§ 69. *Diameters*.—The theorems about the harmonic properties of poles and polars contain, as special cases, a number of important metrical properties of conics. These are obtained if either the pole or the polar is moved to infinity,—it being remembered that the harmonic conjugate to a point at infinity, with regard to two points A, B, is the middle point of the segment AB. The most important properties are stated in the following theorems:—

The middle points of parallel chords of a conic lie in a line—viz., on the polar to the point at infinity on the parallel chords.

This line is called a *diameter*.

The polar of every point at infinity is a diameter.

The tangents at the end points of a diameter are parallel, and are parallel to the chords bisected by the diameter.

All diameters pass through a common point, the pole of the line at infinity.

All diameters of a parabola are parallel, the pole to the line at infinity being the point where the curve touches the line at infinity.

In case of the ellipse and hyperbola, the pole to the line at infinity is a finite point called the *centre* of the curve.

A centre of a conic bisects every chord through it.

The centre of an ellipse is within the curve, for the line at infinity does not cut the ellipse.

The centre of an hyperbola is without the curve, because the line at infinity cuts the curve. Hence also

*From the centre of an hyperbola two tangents can be drawn to the curve which have their points of contact at infinity. These are called *Asymptotes* (§ 59).*

To construct a diameter of a conic, draw two parallel chords and join their middle points.

To find the centre of a conic, draw two diameters; their intersection will be the centre.

§ 70. *Conjugate Diameters*.—A polar-triangle with one vertex at the centre will have the opposite side at infinity. The other two sides pass through the centre, and are called *conjugate diameters*, each being the polar of the point at infinity on the other.

Of two conjugate diameters each bisects the chords parallel to the other, and if one cuts the curve, the tangents at its ends are parallel to the other diameter.

Further—
Every parallelogram inscribed in a conic has its sides parallel to two conjugate diameters; and

Every parallelogram circumscribed about a conic has its diagonals two conjugate diameters.

This will be seen by considering the parallelogram in the first

case as an inscribed four-point, in the other as a circumscribed four-side, and determining in each case the corresponding polar-triangle. The first may also be enunciated thus—

The lines which join any point on an ellipse or an hyperbola to the ends of a diameter are parallel to two conjugate diameters.

§ 71. *THE CIRCLE*.—If every diameter is perpendicular to its conjugate the conic is a circle.

For the line which joins the ends of a diameter to any point on the curve include a right angle.

A circle which has more than one pair of conjugate diameters at right angles to each other is a circle.

Let AA' and BB' (fig. 23) be one pair of conjugate diameters at right angles to each other, CC' and DD' a second pair. If we draw through the end point A of one diameter a chord AP parallel to DD', and join P to A', then PA and PA' are, according to § 70, parallel to two conjugate diameters. But PA is parallel to DD', hence PA' is parallel to CC', and therefore PA and PA' are perpendicular. If we further draw the tangents to the conic at A and A', these will be perpendicular to AA', they being parallel to the conjugate diameter BB'. We know thus five points on the conic, viz., the points A and A' with their tangents, and the point P. Through these a circle may be drawn having AA' as diameter, and as through five points one conic only can be drawn, this circle must coincide with the given conic.

Fig. 23.

§ 72. *Axes*.—Conjugate diameters perpendicular to each other are called *axes*, and the points where they cut the curve *vertices* of the conic.

In a circle every diameter is an axis, every point on it is a vertex, and any two lines at right angles to each other may be taken as a pair of axes of any circle which has its centre at their intersection.

If we describe on a diameter AB of an ellipse or hyperbola a circle concentric to the conic, it will cut the latter in A and B (fig. 24).

Each of the semicircles in which it is divided by AB will be partly within, partly without the curve, and must cut the latter therefore again in a point. The circle and the conic have thus four points A, B, C, D, and therefore one polar-triangle in common (§ 68) of this the centre is one vertex, for the line at infinity is the polar to this point, both with regard to the circle and the other conic. The other two sides are conjugate diameters of both, hence perpendicular to each other. This gives—

Theorem.—An ellipse as well as an hyperbola has one pair of axes.

This reasoning shows at the same time how to construct the axis of an ellipse or of an hyperbola.

A parabola has one axis, if we define an axis as a diameter perpendicular to the chords which it bisects. It is easily constructed. The line which bisects any two parallel chords is a diameter. Chords perpendicular to it will be bisected by a parallel diameter, and this is the axis.

§ 73. The first part of the right hand theorem in § 64 may be stated thus: two any two conjugate lines through a point P without a conic are harmonic conjugates with regard to the two tangents that may be drawn from P to the conic.

If we take instead of P the centre C of an hyperbola, then the conjugate lines become conjugate diameters, and the tangents asymptotes. Hence—

Theorem.—Any two conjugate diameters of an hyperbola are harmonic conjugates with regard to the asymptotes.

As the axes are conjugate diameters at right angles to one another, it follows (§ 29)—

Theorem.—The axes of an hyperbola bisect the angles between the asymptotes.

Let O be the centre of the hyperbola (fig. 25), t any secant which cuts the hyperbola in C, D and the asymptotes in E, F, then the line OH which bisects the chord CD is a diameter conjugate to the diameter OK which is parallel to the secant t, so that OK and OM

Fig. 24.

are harmonic with regard to the asymptotes. The point M therefore bisects EF. But by construction M bisects CD. It follows that $DF = EC$, and $ED = CF$, or

Fig. 25

THEOREM—*On any secant of an hyperbola the segments between the curve and the asymptotes are equal*

If the chord is changed into a tangent, this gives

The segment between the asymptotes on any tangent to an hyperbola is bisected by the point of contact

The first part allows a simple solution of the problem to find any number of points on an hyperbola, of which the asymptotes and one point are given. This is equivalent to three points and the tangents at two of them. This construction requires measurement.

§ 74 For the parabola, too, follow some metrical properties. A diameter PM (fig. 26) bisects every chord conjugate to it, and the pole P of such a chord BC lies on the diameter. But a diameter cuts the parabola once at infinity. Hence—

Theorem.—*The segment PM which joins the middle point M of a chord of a parabola to the pole P of the chord is bisected by the parabola at A.*

§ 75 Two asymptotes and any two tangents to an hyperbola may be considered as a quadrilateral circumscribed about the hyperbola. But in such a quadrilateral the intersections of the

Fig. 26.

Fig. 27.

diagonals and the points of contact of opposite sides lie in a line (§ 64). If therefore DEFG (fig. 27) is such a quadrilateral, then the diagonals DF and GE will meet on the line which joins the points of contact of the asymptotes, that is, on the line at infinity; hence

they are parallel. From this the following theorem is a simple deduction—

Theorem—*All triangles formed by a tangent and the asymptotes of an hyperbola are equal in area.*

If we draw at a point P (fig. 27) on an hyperbola a tangent, the part HK between the asymptotes is bisected at P. The parallelogram PQOQ' formed by the asymptotes and lines parallel to them through P will be half the triangle OHK, and will therefore be constant. If we now take the asymptotes OX and OY as oblique axes of coordinates, the lines OQ and Q'P will be the coordinates of P, and will satisfy the equation $xy = \text{const.} = a^2$.

Theorem—*For the asymptotes as axes of coordinates the equation of the hyperbola is*

$$xy = \text{const.}$$

It is not difficult to get the equations to the ellipse and hyperbola referred to then axes as axes of coordinates. We are satisfied to have shown in one case that the curves of the second order as generated by projective pencils are the same as those which are in coordinate geometry defined by equations of the second degree.

INVOLUTION

§ 76 If we have two projective rows, ABC on u and A'B'C' on u' , and place them both bases on the same line, then each point in this line counts twice, once as a point in the row u and once as a point in the row u' . In fig. 28 we denote the points as points in the one row by letters above the line A, B, C, . . . and as points in the second row by A', B', C', . . . below the line. Let now A and B' be the same point, then to A will correspond a point A' in the second, and to B' a point B in the first row. In general these points A' and B will be different. If may, however, happen that they coincide. Then the correspondence is a peculiar one, as the following theorem shows—

THEOREM—*If two projective rows lie on the same base, and if it happens that to one point in the base the same point corresponds, whether we consider the point as belonging to the first or to the second row, then the same will happen for every point in the base—that is to say, to every point in the line corresponds the same point in the first as in the second row.*

Proof. In order to determine the correspondence, we may assume three pairs of corresponding points in two projective rows. Let them A', B', C', in fig. 29, correspond to A, B, C, so that A and B', and also B and A', denote the same point. Let us further denote the point C when considered as a point in the first row by D;

then it is to be proved that the point D', which corresponds to D, is the same point as C. We know that the cross-ratio of four points is equal to that of the corresponding row. Hence

$$(ABCD) = (A'B'C'D')$$

but replacing the dashed letters by those undashed ones which denote the same points, the second cross-ratio equals (BADD'), which, according to § 15, iv., equals (ABD'D); so that the equation becomes

$$(ABCD) = (ABD'D)$$

This requires that C and D' coincide.

§ 77. Two projective rows on the same base, which have the above property, that to every point, whether it be considered as a point in the one or in the other row, corresponds the same point, are said to be in *involution*, or to form an *involution* of points on the line.

We mention, without proving it, that any two projective rows may be placed so as to form an involution.

An involution may be said to consist of a row of pairs of points, to every point A corresponding a point A', and to A' again the point A. These points are said to be conjugate.

From the definition, according to which an involution may be considered as made up of two projective rows, follow at once the following important properties—

(1) The cross-ratio of four points equals that of the four conjugate points

(2) If we call a point which coincides with its conjugate point a "focus" of the involution, we may say: An involution has either two foci, or one, or none, and is called respectively a hyperbolic, parabolic, or elliptic involution (§ 84)

(3) In a hyperbolic involution any two conjugate points are harmonic conjugates with regard to the two foci

For if A, A' be two conjugate points, F₁, F₂ the two foci, then to the points F₁, F₂, A, A' in the one row correspond the points F₁, F₂, A', A in the other, each focus corresponding to itself. Hence $(F_1 F_2 A A') = (F_2 F_1 A' A)$ —that is, we may interchange the two points A, A' without altering the value of the cross-ratio, which is the characteristic property of harmonic conjugates (§ 18).

(4) The point conjugate to the point at infinity is called the "centre" of the involution. Every involution has a centre, unless the point at infinity be a focus, in which case we may say that the centre is at infinity.

In a hyperbolic involution the centre is the middle point between the foci.

(5) The product of the distances of two conjugate points A, A' from the centre O is constant —

$$OA \cdot OA' = c^2$$

Proof—Let A, A' , and B, B' be two pairs of conjugate points, O the centre, I the point at infinity, then

$$(ABOI) = (A'B'IO),$$

or

$$OA \cdot OA' = OB \cdot OB'.$$

In order to determine the distances of the foci from the centre, we write F for A and A' and get

$$OF^2 = c^2, OF = \pm \sqrt{c^2}.$$

Hence if c is positive OF is real, and has two values, equal and opposite. The involution is hyperbolic.

If $c=0$, $OF=0$, and the two foci both coincide with the centre.

If c is negative, $\sqrt{c^2}$ becomes imaginary, and there are no foci. Hence we may write—

In a hyperbolic involution, $OA \cdot OA' = l^2$,

In a parabolic involution, $OA \cdot OA' = 0$,

In an elliptic involution, $OA \cdot OA' = -l^2$.

From these expressions it follows that conjugate points A, A' in a hyperbolic involution lie on the same side of the centre, and in an elliptic involution on opposite sides of the centre, and that in a parabolic involution one coincides with the centre.

In the first case, for instance, $OA \cdot OA'$ is positive, hence OA and OA' have the same sign.

It also follows that two segments, AA' and BB' , between pairs of conjugate points have the following properties—In a hyperbolic involution they lie either one altogether within or altogether without each other, in a parabolic involution they have one point in common, and in an elliptic involution they overlap, each being partly within and partly without the other.

Proof—We have $OA \cdot OA' = OB \cdot OB' = l^2$ in case of a hyperbolic involution. Let A and B be the points in each pair which are nearer to the centre O . If A, A' and B, B' lie on the same side of O , and if B is nearer to O than A , so that $OB < OA$, then $OB' > OA'$, hence B' has further away from O than A' , or the segment AA' lies within BB' . And so on for the other cases.

(6) An involution is determined—

- By two pairs of conjugate points. Hence also
- By one pair of conjugate points and the centre,
- By the two foci,
- By one focus and one pair of conjugate points,
- By one focus and the centre.

(7) The condition that A, B, C and A', B', C' may form an involution may be written in one of the forms—

$$(ABCC') = (A'B'C'A'),$$

or

$$(ABCA') = (A'B'CA),$$

or

$$(\Delta BCA') = (\Delta B'CA),$$

for each expresses that in the two projective rows in which A, B, C and A', B', C' are conjugate points two conjugate elements may be interchanged.

(8) Any three pairs, A, A', B, B', C, C' , of conjugate points are connected by the relation—

$$\frac{BA'}{AC} \cdot \frac{CB'}{BA} \cdot \frac{AC'}{CB} = -1.$$

Proof—We have by (7) $(ABC'A') = (A'B'CA)$, which, when worked out, gives the above relation.

The latter is easily remembered by aid of the following rule of writing the first side First write

$$\frac{B}{C} \cdot \frac{A}{A'} \cdot \frac{B'}{B},$$

and then fill up the gaps in numerator and denominator by A', B', C' respectively.

§ 78. THEOREM.—The sides of any four-point are cut by any line in six points in involution, opposite sides being cut in conjugate points.

Let A, B, C, D (fig. 30) be the four-point. If its sides be cut by the line p in the points A', B', C', D' , if further, C, D cuts the line AA', B, C and if we project the row A, B, C, D to p once from D_1 and once from C_1 , we get

$$(B'C'O) = (B'A'C'O).$$

Interchanging in the last cross-ratio the letters in each pair we get

$$(A'B'C'O) = (ABCO).$$

Hence by § 77 (7) the points are in involution.

The theorem may also be stated thus —

Theorem—The three points in which any line cuts the sides of a triangle and the projections, from any point in the plane, of the vertices of the triangle on to the same line are six points in involution.

Or again—

The projections from any point on to any line of the six vertices

Fig 30.

of a four-side are six points in involution, the projections of opposite vertices being conjugate points.

This property gives a simple means to construct, by aid of the straight edge only, in an involution, of which two pairs of conjugate points are given, to any point its conjugate.

§ 79. The theory of involution may at once be extended from the row to the flat and the axial pencil—viz, we say that there is an involution in a flat or in an axial pencil if any line cuts the pencil in an involution of points. An involution in a pencil consists of pairs of conjugate rays or planes, it has two, one, or no focal rays or planes, but nothing corresponding to a centre.

An involution in a flat pencil contains always one, and in general only one, pair of conjugate rays which are perpendicular to one another. For in two projective flat pencils exist always two corresponding right angles (§ 40).

Each involution in an axial pencil contains in the same manner one pair of conjugate planes at right angles to one another.

As a rule, there exists but one pair of conjugate lines or planes at right angles to each other. But it is possible that there are more, and then there is an infinite number of such pairs. An involution in a flat pencil, in which every ray is perpendicular to its conjugate ray, is said to be *circular*. That such involution is possible is easily seen thus—if in two concentric flat pencils each ray on one is made to correspond to that ray on the other which is perpendicular to it, then the two pencils are projective, for if we turn the one pencil through a right angle each ray in one coincides with its corresponding ray in the other. But these two projective pencils are in involution.

A circular involution has no focal rays, because no ray in a pencil coincides with the ray perpendicular to it.

§ 80. THEOREM.—Every elliptical involution in a row may be considered as a section of a circular involution.

Proof—In an elliptical involution any two segments AA' and BB' lie partly within partly without each other (fig. 31). Hence two circles described on AA' and BB' as diameters will intersect in two points E and E' .

The line EE' cuts the base of the involution at a point O , which, from a well known proposition (Euc. III. 35), has the property that $OA \cdot OA' = OB \cdot OB'$, for each is equal to $OE \cdot OE'$. The point O is therefore the centre of the involution. If we wish to construct to any point C the conjugate point C' , we may draw the circle through CEE' . This will cut the base in the required point C' for $OC \cdot OC' = OA \cdot OA'$, but EC and EC' are at right angles. Hence the involution which is obtained by joining E or E' to the points in the given involution is circular. This may also be expressed thus:—

Every elliptical involution has the property that there are two definite points in the plane from which any two conjugate points are seen under a right angle.

Fig. 31.

At the same time the following problem has been solved —

Problem.—To determine the centre and also the point corresponding to any given point in an elliptical involution of which two pairs of conjugate points are given.

§ 81. By the aid of § 53, the points on a conic may be made to correspond to those on a line, so that the row of points on the conic is projective to a row of points on a line. We may also have two projective rows on the same conic, and these will be in involution as soon as one point on the conic has the same point corresponding to it all the same to whatever row it belongs. An involution of points on a conic will have the property (as follows from its definition, and from § 53) that the lines which join conjugate points of the involution to any point on the conic are conjugate lines of an involution in a pencil, and that a fixed tangent is cut by the tangents at conjugate points on the conic in points which are again conjugate points of an involution on the fixed tangent. For such involution on a conic the following theorem holds:—

THEOREM.—*The lines which join corresponding points in an involution on a conic all pass through a fixed point, and reciprocally, the points of intersection of conjugate lines in an involution among tangents to a conic lie on a line.*

We prove the first part only. The involution is determined by two pairs of conjugate points, say by A, A' and B, B' (fig. 32). Let AA' and BB' meet in P . If we join the points in involution to any point on the conic, and the conjugate points to another point on the conic,

Fig. 32.

we obtain two projective pencils. We take A and A' as centres of these pencils, so that the pencils $A(A'B'B')$ and $A'(A'B'B')$ are projective, and in perspective position, because AA' corresponds to $A'A$. Hence corresponding rays meet in a line, of which two points are found by joining AB' to $A'B$ and AB to $A'B'$. It follows that the axis of perspective is the polar of the point P , where AA' and BB' meet. If we now wish to construct to any other point C on the conic the corresponding point C' , we join C to A' and the point where this line cuts p to A . The latter line cuts the conic again in C' . But we know from the theory of pole and polar that the line CC' passes through P .

INVOLUTION DETERMINED BY A CONIC ON A LINE.—FOCI.

§ 82. The polars, with regard to a conic, of points in a row p form a pencil P projective to the row (§ 66). This pencil cuts the base of the row p in a projective row.

If A is a point in the given row, A' the point where the polar of A cuts p , then A and A' will be corresponding points. If we take A' a point in the first row, then the polar of A' will pass through A , so that A corresponds to A' —in other words, the rows are in involution. The conjugate points in this involution are conjugate points with regard to the conic. Conjugate points coincide only if the polar of a point A passes through A —that is, if A lies on the conic. Hence—

THEOREM.—*A conic determines on every line in its plane an involution, in which those points are conjugate which are also conjugate with regard to the conic.*

If the line cuts the conic the involution is hyperbolic, the points of intersection being the foci.

If the line touches the conic the involution is parabolic, the two foci coinciding at the point of contact.

If the line does not cut the conic the involution is elliptic, having no foci.

If, on the other hand, we take a point P in the plane of a conic, we get to each line a through P one conjugate line which joins P to the pole of a . These pairs of conjugate lines through P form an involution in the pencil at P . The focal rays of this involution are the tangents drawn from P to the conic. This gives the theorem reciprocal to the last, viz. :—

THEOREM.—*A conic determines in every pencil as its plane an involution, corresponding lines being conjugate lines with regard to the conic.*

If the point is without the conic the involution is hyperbolic, the tangents from the points being the focal rays.

If the point lies on the conic the involution is parabolic, the tangent at the point counting for coincident focal rays.

If the point is within the conic the involution is elliptic, having no focal rays.

It will further be seen that the involution determined by a conic on any line p is a section of the involution, which is determined by the conic at the pole P of p .

§ 83. Definition.—The centre of a pencil in which the conic determines an enular involution is called a “focus” of the conic.

In other words—

A focus is such a point that every line through it is perpendicular to its conjugate line.

The pole to a focus is called a directrix of the conic.

From the definition it follows that —

Every focus lies on an axis, for the line joining a focus to the centre of the conic is a diameter to which the conjugate lines are perpendicular; and

Every line joining two foci is an axis, for the perpendiculars to this line through the foci are conjugate to it. These conjugate lines pass through the pole of the line, the pole lies therefore at infinity, and the line is a diameter, hence by the last property an axis.

It follows that all foci lie on one axis, for no line joining a point in one axis to a point in the other can be an axis.

As the conic determines in the pencil which has its centre at a focus a circular involution, no tangents can be drawn from the focus to the conic. Hence each focus lies within a conic, and a directrix does not cut the conic.

Further properties are found by the following considerations. — § 84. Through a point P one line g can be drawn, which is with regard to a given conic conjugate to a given line g , viz. that line which joins the point P to the pole of the line g . If the line g is made to describe a pencil about a point Q , then the line g will describe a pencil about P . These two pencils will be projective, for the line p passes through the pole of g , and whilst g describes the pencil Q , its pole describes a projective row, and this row is perspective to the pencil P .

We now take the point P on an axis of the conic, draw any line p through it, and from the pole of p draw a perpendicular q to p . Let q cut the axis in Q . Then, in the pencils of conjugate lines, which have their centres at P and Q , the lines p and q are conjugate lines at right angles to one another. Besides, to the axis as a ray in either pencil will correspond in the other the perpendicular to the axis (§ 72). The conic generated by the intersection of corresponding lines in the two pencils is therefore the circle on PQ as diameter, so that every line in P is perpendicular to its corresponding line in Q .

To every point P on an axis of a conic corresponds thus a point Q , such that conjugate lines through P and Q are perpendicular.

We shall show that these point-pairs P, Q form an involution. To do this let us move P along the axis, and with it the line p , keeping the latter parallel to itself. Then P describes a row, q a perspective pencil (of parallels), and the pole of p a projective row. At the same time the line g describes a pencil of parallels perpendicular to p , and perspective to the row formed by the pole of p . The point Q , therefore, where q cuts the axis, describes a row projective to the row of points P . The two points P and Q describe thus two projective rows on the axis, and not only does P as a point in the first row correspond to Q , but also Q as a point in the first corresponds to P . The two rows therefore form an involution. The centre of this involution, it is easily seen, is the centre of the conic.

A focus of this involution has the property that any two conjugate lines through it are perpendicular; hence, it is a focus to the conic.

Such involution exists on each axis. But only one of these can have foci, because all foci lie on the same axis. The involution on one of the axes is elliptic, and appears (§ 80) therefore as the section of two circular involutions in two pencils whose centres lie in the other axis. These centres are foci, hence the one axis contains two foci, the other axis none; or every central conic has two foci which lie on one axis equidistant from the centre.

The axis which contains the foci is called the principal axis; in case of an hyperbola it is the axis which cuts the curve, because the foci lie within the conic.

In case of the parabola there is but one axis. The involution on this axis has its centre at infinity. One focus is therefore at infinity, the one focus only is finite. A parabola has only one focus.

§ 85. If through any point P (fig. 33) on a conic the tangent PT and the normal PN (i.e., the perpendicular to the tangent through the point of contact) be drawn, these will be conjugate lines with regard to the conic, and at right angles to each other.

They will therefore cut the principal axis in two points, which are conjugate in the involution considered in § 84, hence they are harmonic conjugates with regard to the foci. If therefore the two foci F_1 and F_2 be joined to P , these lines will be harmonic with

Fig. 33.

regard to the tangent and normal. As the latter are perpendicular, they will bisect the angles between the other pair. Hence—

The line joining any point on a conic to the two foci are equally inclined to the tangent and normal at that point.

In case of the parabola this becomes—

The line joining any point on a parabola to the focus and the diameter through the point, are equally inclined to the tangent and normal at that point.

From the definition of a focus it follows that—

The segment of a tangent between the directrix and the point of contact is seen from the focus belonging to the directrix under a right angle, because the lines joining the focus to the ends of this segment are conjugate with regard to the conic, and therefore perpendicular.

With equal ease the following theorem is proved—

The two lines which join the points of contact of two tangents each to one focus, but not both to the same, are seen from the intersection of the tangents under equal angles.

§ 86 Other focal properties of a conic are obtained by the following considerations:—

Let F (fig. 94) be a focus to a conic, f the corresponding directrix, A and B the points of contact of two tangents meeting at T , and P the point where the line AB cuts the directrix. Then TF will be the polar of P (because polars of F and T meet at P). Hence TF

Fig. 34.

and PF are conjugate lines through a focus, and therefore perpendicular. They are further harmonic conjugates with regard to FA and FB (§§ 64 and 13), so that they bisect the angles formed by these lines. This by the way proves—

The segments between the point of intersection of two tangents to a conic and their points of contact are seen from a focus under equal angles.

If we next draw through A and B lines parallel to TF , then the points A_1, B_1 where these cut the directrix will be harmonic conjugates with regard to P and the point where TF cuts the directrix. The lines PT and PF bisect therefore also the angles between FA_1 and FB_1 . From this it follows easily that the triangles FAA_1 and FB_1B are equiangular, and therefore similar, so that

$$FA \cdot AA_1 = FB \cdot BB_1$$

The triangles AA_1A_2 and BB_1B_2 , formed by drawing perpendiculars from A and B to the directrix are also similar, so that $AA_1 \cdot AA_2 = BB_1 \cdot BB_2$.

This, combined with the above proportion, gives

$$FA \cdot AA_2 = FB \cdot BB_2$$

Hence the theorem—

The ratio of the distances of any point on a conic from a focus and the corresponding directrix is constant.

To determine this ratio we consider its value for a vertex on the principal axis. In an ellipse the focus lies between the two vertices on this axis, hence the focus is nearer to a vertex than to the corresponding directrix. Similarly in an hyperbola a vertex is nearer to the directrix than to the focus. In a parabola the vertex lies halfway between directrix and focus.

It follows in an ellipse the ratio between the distance of a point from the focus to that from the directrix is less than unity, in the parabola it equals unity, and in the hyperbola it is greater than unity. It is here the same which focus we take, because the two foci lie symmetrical to the axis of the conic. If now P is any point on the conic having the distances r_1 and r_2 from the foci and the distances d_1 and d_2 from the corresponding directrices, then

$$\frac{r_1}{d_1} = \frac{r_2}{d_2} = e,$$

where e is constant. Hence also $\frac{r_1 \pm r_2}{d_1 \pm d_2} = e$

In the ellipse, which lies between the directrices, $d_1 + d_2$ is constant, therefore also $r_1 + r_2$. In the hyperbola on the other hand $d_1 - d_2$ is constant, equal to the distance between the directrices, therefore in this case $r_1 - r_2$ is constant.

If we call the distances of a point on a conic from the focus its focal distances we have the theorem—

In an ellipse the sum of the focal distances is constant; and in an hyperbola the difference of the focal distances is constant.

This constant sum or difference equals in both cases the length of the principal axis.

PENCIL OF CONICS.

§ 87 Through four points A, B, C, D in a plane, of which no three lie in a line, an infinite number of conics may be drawn, viz., through these four points and any fifth one single conic. This system of conics is called a pencil of conics. Similarly all conics touching four fixed lines form a system such that any fifth tangent determines one and only one conic. We have here the theorems—

Theorem.—The pairs of points in which any line is cut by a system of conics which can be drawn from a point to a system of conics touching four fixed lines are in involution.

Fig. 35.

We prove the first theorem only. Let $ABCD$ (fig. 35) be the four-point, then any line l will cut two opposite sides AC, BD in the points E, E' , the pair AD, BC in two points F, F' , and any conic of the system in M, N , and we have

$$A(CDMN) = B(CDMN).$$

If we cut these pencils by t we get

$$(EFMN) = (F'E'N'M')$$

or

$$(EFMN) = (E'F'N'M').$$

But this is, according to § 77 (7), the condition that M, N are corresponding points in the involution determined by the point pairs E, E', F, F' in which the line t cuts pairs of opposite sides of the four-point $ABCD$. This involution is independent of the particular conic chosen.

§ 88. There follow several important consequences.—

THEOREM—*Through four points two, one, or no conic may be drawn which touch any given line, according as the involution determined by the given four-point on the line has real, coincident, or imaginary foci.*

THEOREM—*Two, one, or no conics may be drawn which touch four given lines and pass through a given point, according as the involution determined by the given four-side at the point has real, coincident, or imaginary focal rays.*

For the conic through four points which touches a given line has its point of contact as a focus of the involution determined by the four-point on the line.

As a special case we get, by taking the line at infinity.—

THEOREM—*The four points of which none is at infinity either two or no parabolas may be drawn.*

The problem of drawing a conic through four points and touching a given line is solved by determining the points of contact on the line, that is, by determining the foci of the involution in which the line cuts the sides of the four point. The corresponding remark holds for the problem of drawing the conics which touch four lines and pass through a given point.

RULED QUADRIC SURFACES

§ 89. Formerly we have considered projective rows which lie in the same plane. In that case, lines joining corresponding points envelope a conic. We shall now consider projective rows whose bases do not meet. In this case, corresponding points will be joined by lines which do not lie in a plane, but on some surface, which like every surface generated by lines is called a ruled surface. This surface clearly contains the bases of the two rows.

If the points in either row be joined to the base of the other, we obtain two axial pencils which are also projective, these pencils being corresponding which pass through corresponding points in the given rows. If A, A' be two corresponding points, a, a' the planes in the axial pencils passing through them, then AA' will be the line of intersection of the corresponding planes a, a' , and also the line joining corresponding points in the rows.

If we cut the whole figure by a plane this will cut the axial pencils in two projective flat pencils, and the curve of the second order generated by these will be the curve in which the plane cuts the surface. Hence

THEOREM—*The locus of lines joining corresponding points in two projective rows which do not lie in the same plane is a surface which contains the bases of the rows, and which can also be generated by the lines of intersection of corresponding planes in two projective axial pencils. This surface is cut by every plane in a curve of the second order, hence either in a conic or in a line-pair. No line which does not lie altogether on the surface can have more than two points in common with the surface, which is therefore said to be of the second order, or is called a ruled quadric surface.*

That no line which does not lie on the surface can cut the surface in more than two points is seen at once if a plane be drawn through the line, for this will cut the surface in a conic. It follows also that

A line which contains more than two points of the surface lies altogether on the surface.

§ 90. Through any point in space one line can always be drawn cutting two given lines which do not themselves meet.

If through three lines in space be given of which no two meet, then through every point in either one line may be drawn cutting the other two.

THEOREM—*If a line moves so that it always cuts three given lines of which no two meet, then it generates a ruled quadric surface.*

Proof.—Let a, b, c be the given lines, and p, q, r, \dots lines cutting them in the points $A, A', A'', \dots, B, B', B'', \dots, C, C', C'', \dots$ respectively; then the planes through a containing p, q, r , and the planes through b containing the same lines, may be taken as corresponding planes in two axial pencils which are projective, because both pencils cut the line c in the same row C, C', C'', \dots ; the surface can therefore be generated by projective axial pencils.

Of the lines p, q, r, \dots no two can meet, for otherwise the lines a, b, c which cut them would also lie in their plane. There is a single infinite number of them, for one passes through each point of a . These lines are said to form a set of lines on the surface.

If now three of the lines p, q, r be taken, then every line d cutting them will have three points in common with the surface, and will therefore lie altogether on it. This gives rise to a second set

of lines on the surface. From what has been said the theorem follows—

THEOREM—*A ruled quadric surface contains two sets of straight lines. Every line of one set cuts every line of the other, but no two lines of the same set meet.*

Any two lines of the same set may be taken as bases of two projective rows, or of two projective pencils which generate the surface. They are cut by the lines of the other set in two projective rows.

The plane at infinity like every other plane cuts the surface either in a conic proper or in a line-pair. In the first case the surface is called an *Hyperboloid of one sheet*, in the second an *Hyperbolic Paraboloid*.

The latter may be generated by a line cutting three lines of which one lies at infinity, that is, cutting two lines and remaining parallel to a given plane.

QUADRIC SURFACES

§ 91. The conics, the cones of the second order, and the ruled quadric surfaces complete the figures which can be generated by projective rows or flat and axial pencils, that is, by those aggregates of elements which are of one dimension (§§ 5, 6). We shall now consider the simpler figures which are generated by aggregates of two dimensions. The space at our disposal will not, however, allow us to do more than indicate a few of the results.

§ 92. We establish a correspondence between the lines and planes in pencils in space, or reciprocally between the points and lines in two or more planes, but consider principally pencils.

In two pencils we may either make pencils correspond to planes and lines to lines, or else planes to lines and lines to planes. If hereby the condition be satisfied that to a flat, or axial, pencil corresponds in the first case a projective flat, or axial, pencil, and in the second a projective axial, or flat, pencil, the pencils are said to be projective in the first case and reciprocal in the second.

For instance, two pencils which join two points S_1 and S_2 to the different points and lines in a given plane π are projective (and in perspective position), if those lines and planes be taken as corresponding which meet the plane π in the same point or in the same line. In this case every plane through both centres S_1 and S_2 of the two pencils will correspond to itself. If these pencils are brought into any other position they will be projective (but not perspective).

The correspondence between two projective pencils is uniquely determined, if to four rays (or planes) in the one the corresponding rays (or planes) in the other are given, provided that no three rays of either set lie in a plane.

Proof.—Let a, b, c, d be four rays in the one, a', b', c', d' the corresponding rays in the other pencil. We shall show that we can find for every ray e in the first a single corresponding ray e' in the second. To the axial pencil $a(b, c, d, \dots)$ formed by the planes which join a to b, c, d, \dots , respectively corresponds the axial pencil $a'(b', c', d', \dots)$, and its correspondence is determined. Hence, the plane $a'd'$ which corresponds to the plane ae is determined. Similarly the plane $b'e'$ may be found and both together determine the ray e' .

Similarly the correspondence between two reciprocal pencils is determined if for four rays in the one the corresponding planes in the other are given.

§ 93. We may now combine—

1. Two reciprocal pencils

Each ray cuts its corresponding plane in a point, the locus of these points is a quadric surface.

2. Two projective pencils

Each plane cuts its corresponding plane in a line, but a ray as a rule does not cut its corresponding ray. The locus of points where a ray cuts its corresponding ray is a twisted cubic. The lines where a plane cuts its corresponding plane are secants.

3. Three projective pencils.

The locus of intersection of corresponding planes is a cubic surface.

Of these we consider only the first two cases.

§ 94. If two pencils are reciprocal, then to a plane in either corresponds a line in the other; to a flat pencil an axial pencil, and so on. Every line cuts its corresponding plane in a point. If S_1 and S_2 be the centres of the two pencils, and P be a point where a line a_1 in the first cuts its corresponding plane a_2 , then the line b_2 in the pencil S_2 which passes through P will meet its corresponding plane b_1 in P . For b_1 is a line in the plane a_1 . The corresponding plane b_2 must therefore pass through the line a_1 , hence through P .

The points in which the lines in S_1 cut the planes corresponding to them in S_2 are therefore the same as the points in which the lines in S_2 cut the planes corresponding to them in S_1 .

The locus of these points is a surface which is cut by a plane in a conic or in a line-pair and by a line in not more than two points unless it lies altogether on the surface. The surface itself is therefore called a quadric surface, or a surface of the second order.

To prove this we consider any line p in space.

The flat pencil in S_1 which lies in the plane drawn through p and the corresponding axial pencil in S_2 determine on p two projective rows, and these points in these which coincide with their corresponding points lie on the surface. But these exist only two, or one, or no such points, unless every point coincides with its corresponding point. In the latter case the line lies altogether on the surface.

This proves also that a plane cuts the surface in a curve of the second order, as no line can have more than two points in common with it. To show that this is a curve of the same kind as those considered before, we have to show that it can be generated by projective flat pencils. We prove first that this is true for any plane through the centre of one of the pencils, and afterwards that every point on the surface may be taken as the centre of such pencil. Let then a_1 be a plane through S_1 . To the flat pencil in S_1 which it contains corresponds in S_2 a projective axial pencil with axis u_2 , and this cuts a_1 in a second flat pencil. These two flat pencils in a_1 are projective, and, in general, neither concentric nor perspective. They generate therefore a conic. But if the line a_2 passes through S_2 , the pencils will have S_2 as common centre, and may therefore have two, or one, or no lines united with their corresponding lines. The section of the surface by the plane a_1 will be accordingly a line-pair or a single line, or else the plane a_1 will have only the point S_1 in common with the surface.

Every line l_1 through S_1 cuts the surface in two points, viz., first in S_1 , and then at the point where it cuts the corresponding plane. If now the corresponding plane passes through S_2 , as in the case just considered, then the two points where l_1 cuts the surface coincide at S_1 , and the line is called a *tangent* to the surface with S_1 as point of contact. Hence if l_1 be a tangent, it lies in that plane τ_1 which corresponds to the line S_2S_1 as a line in the pencil S_2 . The section of this plane has just been considered. It follows that—

All tangents to quadric surface at the centre of one of the reciprocal pencils lie in a plane which is called the tangent plane to the surface at that point as point of contact.

To the line joining the centres of the two pencils as a line in one corresponds in the other the tangent plane at its centre.

The tangent plane to a quadric surface either cuts the surface in two lines, or it has only a single line, or else only a single point in common with the surface.

In the first case the point of contact is said to be hyperbolic, in the second parabolic, in the third elliptic.

§ 95. It remains to be proved that every point P on the surface may be taken as centre of one of the pencils which generate the surface. Let S be any point on the surface Φ generated by the reciprocal pencils S_1 and S_2 . We have to establish a reciprocal correspondence between the pencils S and S_1 , so that the surface generated by them is identical with Φ . To do this we draw two planes a_1 and β_1 through S_1 cutting the surface Φ in two conics which we also denote by a_2 and β_2 . These conics meet at S_1 , and at some other point T where the line of intersection of a_1 and β_1 cuts the surface.

In the pencil S we draw some plane σ which passes through T , but not through S_1 or S_2 . It will cut the two conics first at T , and therefore each at some other point which we call A and B respectively. These we join to S by lines a and b , and now establish the required correspondence between the pencils S and S_1 as follows:—To S_1T shall correspond the plane σ , to the plane a_1 the line a , and to β_1 the line b , hence to the flat pencil in a_1 the axial pencil a . These pencils are made perspective by aid of the conic in a_2 .

In the same manner the flat pencil in β_1 is made perspective to the axial pencil b by aid of the conic in β_2 , corresponding elements being those which meet on the conic. This determines the correspondence, for we know for more than four rays in S_1 the corresponding planes in S . The two pencils S and S_1 thus made reciprocal generate a quadric surface Φ' , which passes through the point S and through the two conics a_2 and β_2 .

The two surfaces Φ and Φ' have therefore the points S and S_1 and the conics a_2 and β_2 in common. To show that they are identical, we draw a plane through S and S_1 cutting each of the conics a_2 and β_2 in two points, which will always be possible. This plane cuts Φ and Φ' in two conics which have the point S and the points where it cuts a_2 and β_2 in common, that is five points in all. The conics therefore coincide.

This proves that all those points P on Φ lie on Φ' which have the property that the plane SS_1P cuts the conics a_2 , β_2 in two points each. If the plane SS_1P has not this property, then we draw a plane SS_1P' . This plane cuts each surface in a conic, and these conics have in common the points S , S_1 , one point on each of the conics a_2 , β_2 , and one point on one of the conics through S and S_1 which lie on both surfaces, hence are five points. They are therefore coincident, and our theorem is proved.

§ 96. The following propositions follow—

A quadric surface has at every point a tangent plane.

Every plane section of a quadric surface is a conic or a line-pair.

Every line which has three points in common with a quadric surface lies on the surface.

Every conic which has five points in common with a quadric surface lies on the surface.

Through two conics which lie in different planes, but have two points in common, and the sixth one external point always one quadric surface may be drawn.

§ 97. *Every plane which cuts a quadric surface in a line pair is a tangent plane.* For every line in this plane through the centre of the line-pair (the point of intersection of the two lines) cuts the surface in two coincident points and is therefore a tangent to the surface, the centre of the line-pair being the point of contact.

If a quadric surface contains a line, then every plane through this line cuts the surface in a line-pair (or in two coincident lines). For this plane cannot cut the surface in a conic. Hence

If a quadric surface contains one line p then it contains an infinite number of lines, and through every point Q on the surface, one line q can be drawn which cuts p . For the plane through the point Q and the line p cuts the surface in a line-pair which must pass through Q and of which p is one line.

No two such lines q on the surface can meet. For as both meet p their plane would contain p and therefore cut the surface in a triangle.

Every line which cuts three lines q will be on the surface, for it has three points in common with it.

Hence the quadric surfaces which contain lines are the same as the ruled quadric surfaces considered in §§ 89-93, but with one important exception. In the last investigation we have left out of consideration the possibility of a plane having only one line (two coincident lines) in common with a quadric surface.

§ 98. To investigate this case we suppose first that there is one point A on the surface through which two different lines a , b can be drawn, which lie altogether on the surface.

If P is any other point on the surface which lies neither on a nor b , then the plane through P and a will cut the surface in a second line a' which passes through P and which cuts a . Similarly there is a line b' through P which cuts b . These two lines a' and b' may coincide, but then they must coincide with PA .

If this happens for one point P , it happens for every other point Q . For if two different lines could be drawn through Q , then by the same reasoning the line PQ would be altogether on the surface, hence two lines would be drawn through P against the assumption. From this follows—

If there is one point on a quadric surface through which one, but only one, line can be drawn on the surface, then through every point one line can be drawn, and all these lines meet in a point. The surface is a cone of the second order.

If through one point on a quadric surface, two, and only two, lines can be drawn on the surface, then through every point two lines may be drawn, and the surface is a ruled quadric surface.

If through one point on a quadric surface no line on the surface can be drawn, then the surface contains no lines.

Using the definitions at the end of § 95, we may also say:—

On a quadric surface the points are all hyperbolic, or all parabolic, or all elliptic.

As an example of a quadric surface with elliptical points, we mention the sphere which may be generated by two reciprocal pencils, where to each line in one corresponds the plane perpendicular to it in the other.

§ 99. *Poles and Polar Planes.*—The theory of poles and polars with regard to a conic is easily extended to quadric surfaces.

Let P be a point in space not on the surface, which we suppose not to be a cone. On every line through P which cuts the surface in two points we determine the harmonic conjugate Q of P with regard to the points of intersection. Through one of these lines we draw two planes a and β . The locus of the points Q in a is a line a , the polar of P with regard to the conic in which a cuts the surface. Similarly the locus of points Q in β is a line β . This cuts a , because the line of intersection of a and β contains but one point Q . The locus of all points Q therefore is a plane. This plane is called the polar plane of the point P , with regard to the quadric surface. If P lies on the surface we take the tangent plane of P as the polar.

The following propositions hold:—

1. *Every point has a polar plane, which is constructed by drawing the polars of the point with regard to the conics in which two planes through the point cut the surface.*

2. *If Q is a point in the polar of P , then P is a point in the polar of Q , because this is true with regard to the conic in which a plane through PQ cuts the surface.*

3. *Every plane is the polar plane of one point, which is called the pole of the plane.*

The pole of a plane is found by constructing the polar planes of three points in the plane. Their intersection will be the pole.

4. *The points in which the polar plane of P cuts the surface are points of contact of tangents drawn from P to the surface, as is easily seen.* Hence:—

PART II.—ANALYTICAL GEOMETRY.

This will be here treated as a method. The science is Geometry; and it would be possible, analytically, or by the method of coordinates, to develop the truths of geometry in a systematic course. But it is proposed not in any way to attempt this, but simply to explain the method, giving such examples, interesting (it may be) in themselves, as are suitable for showing how the method is employed in the demonstration and solution of theorems or problems.

Geometry is one-, two-, or three-dimensional, or, what is the same thing, it is lineal, plane, or solid, according as the space dealt with is the line, the plane, or ordinary (three-dimensional) space. No more general view of the subject need here be taken:—but in a certain sense one-dimensional geometry does not exist, inasmuch as the geometrical constructions for points in a line can only be performed by travelling out of the line into other parts of a plane which contains it, and conformably to the usual practice Analytical Geometry will be treated under the two divisions, Plane and Solid.

It is proposed to consider Cartesian coordinates almost exclusively, for the proper development of the science homogeneous coordinates (three and four in plane and solid geometry respectively) are required, and it is moreover necessary to have the correlative line- and plane-coordinates; and in solid geometry to have the xyz coordinates of the line. The most comprehensive English works are those of Dr Salmon, *The Conics* (5th edition, 1869), *Higher Plane Curves* (2d edition, 1873), and *Geometry of Three Dimensions* (3d edition, 1874); we have also on plane geometry Clebsch's *Vorlesungen über Geometrie*, posthumous, edited by Dr F. Lindemann, Leipzig, 1875, not yet complete.

I. PLANE ANALYTICAL GEOMETRY (§§ 1–25).

1. It is assumed that the points, lines, and figures considered exist in one and the same plane, which plane, therefore, need not be in any way referred to. The position of a point is determined by means of its (Cartesian) coordinates, x, y , as explained under the article CURVE, we take the two lines $x'Ox$ and $y'Oy$, called the axes of x and y respectively, intersecting in a point O called the origin, and determine the position of any other point P by means of its coordinates $x=OM$ (or ON), and $y=MP$ (or ON).

The two axes are usually (as in fig. 1) at right angles to each other, and the lines PM, PN are then at right angles to the axes of x and y respectively. Assuming a scale at pleasure, the coordinates x, y of a point have numerical values.

It is necessary to attend to the signs: x has opposite signs according as the point is on one side or the other of the axis of y , and similarly y has opposite signs according as the point is on the one side or the other of the axis of x . Using the letters N, E, S, W as in a map, and considering the plane as divided into four quadrants by the axes, the signs are usually taken to be—

x	y	for quadr.
+	+	N E
+	–	S E
–	–	N W
–	+	S W

A point is said to have the coordinates (a, b) , and is referred to as the point (a, b) , when its coordinates are $x=a, y=b$; the coordinates x, y of a variable point, or of a point which is for the time being regarded as variable, are said to be current coordinates.

2. It is sometimes convenient to use oblique coordinates, the only difference is that the axes are not at right angles to each other, the lines PM, PN are drawn parallel to the axes of y and x respectively, and the figure $OMPN$ is thus a parallelogram. But in all that follows the Cartesian coordinates are taken to be rectangular, polar coordinates and other systems will be briefly referred to in the sequel.

3. If the coordinates (x, y) of a point are not given, but only a relation between them $f(x, y)=0$, then we have a curve. For, if we consider x as a real quantity varying continuously from $-\infty$ to $+\infty$, then, for any given value of x, y has a value or values. If these are all imaginary, there is not any real point; but if one or more of them be real, we have a real point or points, which (as the assumed value of x varies continuously) varies or vary continuously therewith; and the locus of all these real points is a curve. The equation completely defines the curve, to trace the curve directly from the equation, nothing else being known, we obtain as above a series of points sufficiently near to each other, and draw the curve through them. For instance, let this be done in a simple case. Suppose $y=2x-1$; it is quite easy to obtain and lay down a series of points as near to each other as we please, and the application of a ruler would show that these were in a line, that the curve is a line depends upon something more than the equation itself, viz., the theorem that every equation of the form $y=ax+b$ represents a line; supposing this known, it will be at once understood how the process of tracing the curve may be abbreviated; we have $x=0, y=-1$, and $x=\frac{1}{2}, y=0$; the curve is thus the line passing through these two points. But in the foregoing example the notion of a line is taken to be a known one, and such notion of a line does in fact precede the consideration of any equation of a curve whatever, since the notion of the coordinates themselves rests upon that of a line. In other cases it may very well be that the equation is the definition of the curve; the points laid down, although (as finite in number) they do not actually determine the curve, determine it to any degree of accuracy; and the equation thus enables us to construct the curve.

A curve may be determined in another way; viz., the coordinates x, y may be given each of them as a function of the same variable parameter θ ; $x, y=f(\theta), \phi(\theta)$ respectively. Here, giving to θ any number of values in succession, these equations determine the values of x, y , that is, the positions of a series of points on the curve. The ordinary form $y=\phi(x)$, where y is given explicitly as a function of x , is a particular case of each of the other two forms: we have $f(x, y)=y-\phi(x)=0$; and $x=\theta, y=\phi(\theta)$.

4. As remarked under CURVE, it is a useful exercise to trace a considerable number of curves, first taking equations which are purely numerical, and then equations which contain literal constants (representing numbers); the equations most easily dealt with are those wherein one coordinate is given as an explicit function of the other, say $y=\phi(x)$ as above. A few examples are here given, with such explanations as seem proper.

(1) $y=2x-1$, as before, it is at once seen that this is a line, and taking it to be so, any two points, for instance, $(0, -1)$ and $(\frac{1}{2}, 0)$, determine the line.

(2) $y=x^2$ The equation shows that x may be positive or negative, but that y is always positive, and has the same values for equal positive and negative values of x ; the curve passes through the origin, and through the points $(\pm 1, 1)$. It is already known that the curve lies wholly above the axis of x . To find its form in the neighbourhood of the origin, give x a small value, $x=0.1$ or ± 0.01 , then y is very much smaller, $=0.01$ and 0.0001 in the two cases respectively; this shows that the curve touches the axis of x at the origin. Moreover, x may be as large as we please, but when it is large, y is much larger, for instance, $x=10$, $y=100$. The curve is a parabola (fig. 2)

Fig. 2.

(3) $y=x^3$ Here x being positive y is positive, but x being negative y is also negative; the curve passes through the origin, and also through the points $(1, 1)$ and $(-1, -1)$. Moreover, when x is small, $=0.1$ for example, then not only is $y=0.001$, very much smaller than x , but it is also very much smaller than y was for the last-mentioned curve $y=x^2$; that is, in the neighbourhood of the origin the present curve approaches more closely the axis of x . The axis of x is a tangent at the origin, but it is a tangent of a peculiar kind (a stationary or inflexional tangent), cutting the curve at the origin, which is an inflexion. The curve is the cubical parabola (fig. 3).

Fig. 3.

(4) $y^2=x-1$ or $x-3-4$ Here $y=0$ for $x=1, -3, -4$. Whenever $x-1-3-4$ is positive, y has two equal and opposite values, but when $x-1-3-4$ is negative, then y is imaginary. In particular, for x less than 1, or between 3 and 4, y is imaginary, but for x between 1 and 3, or greater than 4, y has two values. It is clear that for x somewhere between 1 and 3, y will attain a maximum, the values of x and y may be found approximately by trial. The curve will consist of an oval and infinite branch, and it is easy to see that, as shown in fig. 4, the curve where it cuts the axis of x cuts it at right angles. It may be further remarked that, as x increases from 4, the value of y will increase more and more rapidly; for instance, $x=5$, $y^2=8$, $x=10$, $y^2=378$, &c., and it is easy to see that this implies that the curve has on the infinite branch two inflexions as shown.

Fig. 4.

(5) $y^2=x-c-x-b$ or $x-a$, where $a>b>c$ (that is, a is nearer to $+c$, c to $-\infty$). The curve has the same general form as in the last figure, the oval extending between the limits $x=c$ and $x=b$, the infinite branch commencing at the point $x=a$.

(6) $y^2=(x-c)^2(x-a)$. Suppose that in the last-mentioned curve, $y^2=x-c-x-b$ or $x-a$, b gradually diminishes, and becomes ultimately $=c$. The infinite branch (see fig. 5) changes its form, but not in a very marked manner, and it retains the two inflexions. The oval lies always between the values $x=c$, $x=b$, and therefore its length continually diminishes, it is easy to see that its breadth will also continually diminish; ultimately it shrinks up into a mere point. The curve has thus a conjugate or isolated point, or node. For a direct verification observe that $x=c$, $y=0$, so that $(c, 0)$ is a point of the curve, but if x is either less than c , or between c and a , y^2 is negative, and y is imaginary.

Fig. 5.

(7) $y^2=(x-c)(x-a)^2$. If in the same curve b gradually increases and becomes ultimately $=a$, the oval and the infinite branch change each of them its form, the oval extending always between the values $x=c$, $x=b$, and thus continually approaching the infinite branch, which begins at $x=a$. The consideration of a few numerical examples, with careful drawing, would show that the oval and the infinite branch as they approach shape out each towards the other (the two inflexions on the infinite branch coming always nearer to the point $(a, 0)$), so that finally, when b becomes $=a$, the curve has the form shown in fig. 6, there being now a double point or node (crunode) at A , and the inflexions on the infinite branch having disappeared.

Fig. 6.

In the last four examples the curve is one of the cubical curves called the divergent parabolas. 4 is a mere numerical example of 5, and 6, 7, 8 are in Newton's language the parabola *cum ovali*, *punctata*, and *nodata* respectively. When a, b, c are all equal, or the form is $y^2=(x-c)^3$, we have a cuspidal form, Newton's parabola *cuspidata*, otherwise the semicubical parabola.

(8.) As an example of a curve given by an implicit equation, suppose the equation is

$$x^3 + y^3 - 3xy = 0;$$

this is a nodal cubic curve, the node at the origin, and the axes touching the two branches respectively (fig. 7). An easy mode of tracing it is to express x, y each of them in terms of a variable t , $x = \frac{3t}{1+t^3}, y = \frac{3t^2}{1+t^3}$, but it is instructive to trace the curve directly from its equation.

5. It may be remarked that the purely algebraical process, which is in fact that employed in finding a differential coefficient $\frac{dy}{dx}$, if applied directly to the equation of the curve, determines the point consecutive to any given point of the curve, that is, the direction of the curve at such given point, or, what is the same thing, the direction of the tangent at that point. In fact, if α, β are the coordinates of any point on a curve $f(x, y)=0$, then writing in the equation of the curve $x=\alpha+h, y=\beta+k$, and in the resulting equation $f(\alpha+h, \beta+k)=0$ (developed in powers of h and k), omitting the term $f(\alpha, \beta)$, which vanishes, and the terms containing the second and higher powers of h, k , we have a linear equation $Ah+Bk=0$, which determines the ratio of the increments h, k . Of course, in the analytical development of the theory, we translate this into the notation of the differential calculus; but the question presents itself, and is thus seen to be solvable, as soon as it is attempted to trace a curve from its equation.

Geometry is Descriptive, or Metrical.

6. A geometrical proposition is either *descriptive* or *metrical*: in the former case it is altogether independent of the idea of magnitude (length, inclination, &c.); in the latter case it has reference to this idea. It is to be noticed that, although the method of coordinates seems to be by its inception essentially metrical, and we can hardly, except by metrical considerations, connect an equation with the curve which it represents (for instance, even assuming it to be known that an equation $Ax+By+C=0$ represents a line, yet if it be asked what line, the only form of answer is, that it is the line cutting

the axes at *distances* from the origin $-C \div A$, $-C \div B$ respectively, yet in dealing by this method with descriptive propositions, we are, in fact, eminently free from all metrical considerations.

7. It is worth while to illustrate this by the instance of the well-known theorem of the radical centre of three circles. The theorem is that, given any three circles A, B, C (fig. 8), the common chords aa' , $\beta\beta'$, $\gamma\gamma'$ of the three pairs of circles meet in a point.

The geometrical proof is metrical throughout.—

Take O the point of intersection of aa' , $\beta\beta'$, and joining this with γ suppose that γ does not pass through γ' , but that it meets the circles A, B in two distinct points γ_1 , γ_2 respectively. We have then the known metrical property of intersecting chords of a circle, viz. in circle C where aa' , $\beta\beta'$ are chords meeting at a point O,

$$Oa \cdot Oa' = O\beta \cdot O\beta',$$

where, as well as in what immediately follows Oa , &c., denote, of course, *lengths* or *distances*.

Similarly in circle A,

$$O\beta \cdot O\beta' = O\gamma_1 \cdot O\gamma_2,$$

and in circle B,

$$Oa \cdot Oa' = O\gamma_1 \cdot O\gamma_2.$$

Consequently $O\gamma_1 \cdot O\gamma_2 = O\gamma_1 \cdot O\gamma_2$, that is, $O\gamma_1 = O\gamma_2$, or the points γ_1 and γ_2 coincide, that is, they each coincide with γ .

We contrast this with the analytical method.—

Here it only remains to be known that an equation $Ax + By + C = 0$ represents a line, and an equation $x^2 + y^2 + Ax + By + C = 0$ represents a circle A, B, C, have, in the two cases respectively, metrical significations; but these we are not concerned with. Using S to denote the function $x^2 + y^2 + Ax + By + C$, the equation of a circle is $S = 0$, where S stands for its value, more briefly, we say the equation is $S = 0$, or $x^2 + y^2 + Ax + By + C = 0$. Let the equation of any other circle be $S' = 0$, or $x^2 + y^2 + A'x + B'y + C' = 0$, the equation $S - S' = 0$ is a linear equation ($S - S'$ is in fact $(A - A')x + (B - B')y + (C - C')$, and it thus represents a line; this equation is satisfied by the coordinates of each of the points of intersection of the two circles (for at each of these points $S = 0$ and $S' = 0$, therefore also $S - S' = 0$), hence the equation $S - S' = 0$ is that of the line joining the two points of intersection of the two circles, or say it is the equation of the common chord of the two circles. Considering then a third circle $S'' = 0$, or $x^2 + y^2 + A''x + B''y + C'' = 0$, the equations of the common chords are $S - S' = 0$, $S - S'' = 0$, $S' - S'' = 0$ (each of these a linear equation); at the intersection of the first and second of these lines $S - S' = 0$ and $S - S'' = 0$, therefore also $S' - S'' = 0$, or the equation of the third line is satisfied by the coordinates of the point in question; that is, the three chords intersect in a point O, the coordinates of which are determined by the equations $S = S' = S''$.

It further appears that if the two circles $S = 0$, $S' = 0$ do not intersect in any real points, they must be regarded as intersecting in two imaginary points, such that the line joining them is the real line represented by the equation $S - S' = 0$; or that two circles, whether their intersections be real or imaginary, have always a real common chord (or radical axis), and that for any three circles the common chords intersect in a point (of course real) which is the radical centre. And by this very theorem, given two circles with imaginary intersections, we can, by drawing circles which meet each of them in real points, construct the radical axis of the first-mentioned two circles.

8. The principle employed in showing that the equation of the common chord of two circles is $S - S' = 0$ is one of very extensive application, and some more illustrations of it may be given.

Suppose $S = 0$, $S' = 0$ are lines (that is, let S, S' now denote linear functions $Ax + By + C$, $A'x + B'y + C'$), then $S - kS' = 0$ (k an arbitrary constant) is the equation of any line passing through the point of intersection of the two given lines. Such a line may be

made to pass through any given point, say the point (x_0, y_0) , &c., if S_0, S'_0 are what S, S' respectively become on writing for (x, y) the values (x_0, y_0) then the value of k is $k = S_0 - S'_0$. The equation in fact is $SS_0 - S'_0S'_0 = 0$; and starting from this equation we at once verify it a posteriori, the equation is a linear equation satisfied by the values of (x, y) which make $S = 0$, $S' = 0$, and satisfied also by the values (x_0, y_0) and it is thus the equation of the line in question.

If, as before, $S = 0$, $S' = 0$ represent circles, then (k being arbitrary) $S - kS' = 0$ is the equation of any circle passing through the two points of intersection of the two circles, and to make this pass through a given point (x_0, y_0) we have again $k = S_0 - S'_0$. In the particular case $k = 1$, the circle becomes the common chord (more accurately, it becomes the common chord together with the line infinity, but this is a question which is not here gone into).

If S denote the general quadric function,

$S = ax^2 + 2hxy + by^2 + 2fx + 2gy + c$, $(a, b, c, f, g, h)(x, y, 1)^2$, then the equation $S = 0$ represents a conic; assuming this, then, if $S' = 0$ represents another conic, the equation $S - kS' = 0$ represents any conic through the four points of intersection of the two conics. Returning to the equation $Ax + By + C = 0$ of a line, if this pass through two given points (x_1, y_1) , (x_2, y_2) , then we must have $Ax_1 + By_1 + C = 0$, $Ax_2 + By_2 + C = 0$, equations which determine the ratios A : B : C, and it thus appears that the equation of the line through the two given points is

$$x(y_1 - y_2) - y(x_1 - x_2) + x_1y_2 - x_2y_1 = 0,$$

or what is the same thing—

$$\begin{vmatrix} x & y & 1 \\ x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \end{vmatrix} = 0;$$

9. The object still being to illustrate the mode of working with coordinates, we consider the theorem of the polar of a point in regard to a circle. Given a circle and a point O (fig. 9), we draw through O any two lines meeting the circle in the points A, A' and B, B' respectively, and then taking Q as the intersection of the lines AB' and A'B, the theorem is that the locus of the point Q is a right line depending only upon O and the circle, but independent of the particular lines OAA' and OBB'.

Fig. 9

Taking O as the origin, and for the axes any two lines through O at right angles to each other, the equation of the circle will be

$$x^2 + y^2 + 2Ax + 2By + C = 0,$$

and if the equation of the line OAA' is taken to be $y = mx$, then the points A, A' are found as the intersections of the straight line with the circle; or to determine x we have

$$x^2(1 + m^2) + 2x(A + Bm) + C = 0.$$

If (x_1, y_1) are the coordinates of A, and (x_2, y_2) of A', then the roots of this equation are x_1, x_2 , whence easily

$$\frac{1}{x_1} + \frac{1}{x_2} = -2 \frac{A + Bm}{C}.$$

And similarly, if the equation of the line OBB' is taken to be $y = m'x$, and the coordinates of B, B' to be (x_3, y_3) and (x_4, y_4) respectively, then

$$\frac{1}{x_3} + \frac{1}{x_4} = -2 \frac{A + Bm'}{C}.$$

We have then

$$\frac{x(y_1 - y_2) - y(x_1 - x_2) + x_1y_2 - x_2y_1}{x(y_3 - y_4) - y(x_3 - x_4) + x_3y_4 - x_4y_3} = 0,$$

as the equations of the lines AB' and A'B respectively; for the first of these equations, being satisfied if we write therein (x_3, y_3) or (x_4, y_4) for (x, y) , is the equation of the line AB', and similarly the second equation is that of the line A'B. Reducing by means of the relations $y_1 = mx_1$, $y_2 = mx_2$, $y_3 = m'x_3$, $y_4 = m'x_4$, the two equations become

$$\frac{x(mx_1 - m'x_2) - y(x_1 - x_2) + (m' - m)x_1x_2}{x(mx_3 - m'x_4) - y(x_3 - x_4) + (m' - m)x_3x_4} = 0,$$

and if we divide the first of these equations by m_1m_2 , and the second by m_3m_4 , and then add, we obtain

$$x \left\{ m \left(\frac{1}{x_3} + \frac{1}{x_4} \right) - m' \left(\frac{1}{x_1} + \frac{1}{x_2} \right) \right\} - y \left\{ \frac{1}{x_3} + \frac{1}{x_4} - \left(\frac{1}{x_1} + \frac{1}{x_2} \right) \right\} + \frac{2m' - 2m}{m_1m_2} = 0,$$

or, what is the same thing,

$$\left(\frac{1}{x_1} + \frac{1}{x_2}\right)(y - m'x) - \left(\frac{1}{x_3} + \frac{1}{x_4}\right)(y - mx) + 2m' - 2m = 0,$$

which by what precedes is the equation of a line through the point Q. Substituting herein for $\frac{1}{x_1} + \frac{1}{x_2}$, $\frac{1}{x_3} + \frac{1}{x_4}$ their foregoing values, the equation becomes

$$-(A + Bm)(y - m'x) + (A + Bm')(y - mx) + m' - m = 0,$$

that is,

$$(m - m')(Ax + By + C) = 0;$$

or finally it is $Ax + By + C = 0$, showing that the point Q lies in a line the position of which is independent of the particular lines OAA' , OBB' used in the construction. It is proper to notice that there is no correspondence to each other of the points A , A' and B , B' , the grouping might as well have been A , A' and B' , B , and it thence appears that the line $Ax + By + C = 0$ just obtained is in fact the line joining the point Q with the point R which is the intersection of AB and $A'B'$.

10. The equation $Ax + By + C = 0$ of a line contains in appearance 3, but really only 2 constants (for one of the constants can be divided out), and a line depends accordingly upon 2 parameters, or can be made to satisfy 2 conditions. Similarly, the equation $(a, b, c, f, g, h, x, y, 1)^2 = 0$ of a conic contains really 5 constants, and the equation $(x, y, 1)^3 = 0$ of a cubic contains really 9 constants. It thus appears that a cubic can be made to pass through 9 given points, and that the cubic so passing through 9 given points is completely determined. There is, however, a remarkable exception. Considering two given cubic curves $S = 0$, $S' = 0$, these intersect in 9 points, and through these 9 points we have the whole series of cubics $S - kS' = 0$, where k is an arbitrary constant: k may be determined so that the cubic shall pass through a given tenth point ($k = S_0 - S'_0$, if the coordinates are (x_0, y_0)), and S_0, S'_0 denote the corresponding values of S, S' . The resulting curve $SS'_0 - S'S_0 = 0$ may be regarded as the cubic determined by the conditions of passing through 8 of the 9 points and through the given point (x_0, y_0) ; and from the equation it thence appears that the curve passes through the remaining one of the 9 points. In other words, we thus have the theorem, any cubic curve which passes through 8 of the 9 intersections of two given cubic curves passes through the 9th intersection.

The applications of this theorem are very numerous, for instance, we derive from it Pascal's theorem of the inscribed hexagon. Consider a hexagon inscribed in a conic. The three alternate sides constitute a cubic, and the other three alternate sides another cubic. The cubics intersect in 9 points, being the 6 vertices of the hexagon, and the 3 Pascalian points, or intersections of the pairs of opposite sides of the hexagon. Drawing a line through two of the Pascalian points, the conic and this line constitute a cubic passing through 8 of the 9 points of intersection, and it therefore passes through the remaining point of intersection—that is, the third Pascalian point; and since obviously this does not lie on the conic, it must lie on the line—that is, we have the theorem that the three Pascalian points (or points of intersection of the pairs of opposite sides) lie on a line.

Metrical Theory.

11. The foundation of the metrical theory consists in the simple theorem that if a finite line PQ (fig. 10) be projected upon any other line OO' by lines perpendicular to OO' , then the length of the projection $P'Q'$ is equal to the length of PQ into the cosine of its inclination to $P'Q'$; or, what is the same thing, that the perpendicular distance $P'Q'$ of any two parallel lines is equal to the inclined distance PQ into the cosine of the inclination. It at once follows that the algebraical sum of the projections of the sides of a closed polygon upon any line is = 0; or, reversing the signs of certain sides, and considering the

polygon as consisting of two broken lines, each extending from the same initial to the same terminal point, the sum of the projections of the lines of the first set upon any line is equal to the sum of the projections of the lines of the second set. Observe that if any line be perpendicular to the line on which the projection is made, then its projection is = 0.

Thus, if we have a right-angled triangle PQR (fig. 11), where QR, RP, QP are = ξ, η, ρ respectively, and whereof the base-

Fig. 10.

Fig. 11

angle is = α , then projecting successively on the three sides, we have

$$\xi = \rho \cos \alpha, \eta = \rho \sin \alpha, \rho = \xi \cos \alpha + \eta \sin \alpha,$$

and we thence obtain

$$\rho^2 = \xi^2 + \eta^2; \cos^2 \alpha + \sin^2 \alpha = 1.$$

And again, by projecting on a line Qx_1 , inclined at the angle α' to QR, we have

$$\rho \cos (\alpha - \alpha') = \xi \cos \alpha' + \eta \sin \alpha',$$

and by substituting for ξ, η their foregoing values,

$$\cos (\alpha - \alpha') = \cos \alpha \cos \alpha' + \sin \alpha \sin \alpha'.$$

It is to be remarked that, assuming only the theory of similar triangles, we have herein a *proof* of Euclid, Book I, Prop. 47, in fact, the same as is given Book VI, Prop. 31, and also a *proof* of the trigonometrical formula for $\cos (\alpha - \alpha')$. The formulæ for $\cos (\alpha + \alpha')$ and $\sin (\alpha \pm \alpha')$ could be obtained in the same manner.

Draw PT at right angles to Qx_1 , and suppose QT, TP = ξ, η respectively, so that we have now the quadrilateral QRTPT, or, what is the same thing, the two broken lines QRP and QTP, each extending from Q to P. Projecting on the four sides successively, we have

$$\xi = \xi_1 \cos \alpha' - \eta_1 \sin \alpha',$$

$$\eta = \xi_1 \sin \alpha' + \eta_1 \cos \alpha',$$

$$\xi = \xi_1 \cos \alpha' + \eta_1 \sin \alpha',$$

$$\eta_1 = -\xi \sin \alpha' + \eta \cos \alpha',$$

where the third equation is that previously written

$$\rho \cos (\alpha - \alpha') = \xi \cos \alpha' + \eta \sin \alpha'$$

Equations of Right Line and Circle.—Transformation of Coordinates.

12. The required formulæ are really contained in the foregoing results. For, in fig. 11, supposing that the axis of x is parallel to QR, and taking a, b for the coordinates of Q, and (x, y) for those of P, then we have $\xi, \eta = x - a, y - b$ respectively; and therefore

$$x - a = \rho \cos \alpha, \quad y - b = \rho \sin \alpha,$$

$$\rho^2 = (x - a)^2 + (y - b)^2.$$

Writing the first two of these in the form

$$\frac{x - a}{\rho} = \cos \alpha, \quad \frac{y - b}{\rho} = \sin \alpha,$$

we may regard Q as a fixed point, but P as a point moving in the direction Q to P, so that α remains constant, and then, omitting the equation $(-\rho)$, we have a relation between the coordinates x, y of the point P thus moving in a right line,—that is, we have the equation of the line through the given point (a, b) in a given

inclination α to the axis of x . And, moreover, if, using this equation ($=p$), we write $x=a+p \cos \alpha$, $y=b+p \sin \alpha$, then we have expressions for the coordinates x , y of a point of this line, in terms of the variable parameter p .

Again, take the point T to be fixed, but consider the point P as moving in the line TP at right angles to QT . If instead of ξ , we take p for the distance QT , then the equation $\xi=\xi \cos \alpha'+\eta \sin \alpha'$ will be

$$(x-a) \cos \alpha + (y-b) \sin \alpha = p,$$

that is, this will be the equation of a line such that its perpendicular distance from the point (a, b) is $=p$, and that the inclination of this distance to the axis of x is $=\alpha$.

From either form it appears that the equation of a line is, in fact, a linear equation of the form $Ax+By+C=0$. It is important to notice that, starting from this equation, we can determine conversely the a but not the (a, b) of the form of equation which contains these quantities, and in like manner the a' but not the (a, b) or p of the other form of equation. The reason is obvious. In each case (a, b) denote the coordinates of a point, fixed indeed, but which is in the first form any point of the line, and in the second form any point whatever. Thus, in the second form the point from which the perpendicular is let fall may be the origin. Here $(a, b)=(0, 0)$, and the equation is $x \cos \alpha + y \sin \alpha - p = 0$. Comparing this with $Ax+By+C=0$, we have the values of $\cos \alpha$, $\sin \alpha$, and p .

13. The equation

$$p^2 = (x-a)^2 + (y-b)^2$$

is an expression for the squared distance of the two points (a, b) and (x, y) . Taking as before the point Q , coordinates (a, b) , as a fixed point, and writing c in the place of p , the equation

$$(x-a)^2 + (y-b)^2 = c^2$$

expresses that the point (x, y) is always at a given distance c from the given point (a, b) ; viz, this is the equation of a circle, having (a, b) for the coordinates of its centre, and c for its radius.

The equation is of the form

$$x^2 + y^2 + 2Ax + 2By + C = 0,$$

and here, the number of constants being the same, we can identify the two equations; we find $A = -A$, $B = -B$, $C = A^2 + B^2 - C$, or the last equation is that of a circle having $-A, -B$ for the coordinates of its centre, and $\sqrt{A^2 + B^2 - C}$ for its radius.

14. Drawing (fig. 11) Qx_1 at right angles at Qx_1 , and taking Qx_1, Qy_1 as a new set of rectangular axes, if instead of ξ, η we write x_1, y_1 , we have x_1, y_1 as the new coordinates of the point P ; and writing also α in place of α' (α now denoting the inclination of the axes Qx_1 and Ox_1), we have the formulae for transformation between two sets of rectangular axes. These are

$$\begin{aligned} x - a &= x_1 \cos \alpha - y_1 \sin \alpha, \\ y - b &= x_1 \sin \alpha + y_1 \cos \alpha, \end{aligned}$$

and

$$\begin{aligned} x_1 &= (x-a) \cos \alpha + (y-b) \sin \alpha, \\ y_1 &= -(x-a) \sin \alpha + (y-b) \cos \alpha, \end{aligned}$$

each set being obviously at once deducible from the other one. In these formulae (a, b) are the xy -coordinates of the new origin Q_1 , and α is the inclination of Qx_1 to Ox . It is to be noticed that Qx_1, Qy_1 are so placed that, by moving O to Q , and then turning the axes Ox_1, Oy_1 round Q (through an angle α measured in the sense Ox to Oy), the original axes Ox, Oy will come to coincide with Qx_1, Qy_1 respectively. This could not have been done if Qy_1 had been drawn (at right angles always to Qx_1) in the reverse direction, we should then have had in the formulae $-y_1$ instead of y_1 . The new formulae which would be thus obtained are of an essentially distinct form: the analytical test is that in the formulae as written

down we can, by giving to α a proper value (in fact $\alpha=0$), make the $(x-a)$ and $(y-b)$ equal to x_1 and y_1 respectively, in the other system we could only make them equal to $x_1 - y_1$ or $-x_1, y_1$ respectively. But for the very reason that the second system can be so easily derived from the first, it is proper to attend exclusively to the first system,—that is, always to take the new axes so that the two sets admit of being brought into coincidence.

In the foregoing system of two pairs of equations, the first pair give the original coordinates x, y in terms of the new coordinates x_1, y_1 ; the second pair the new coordinates x_1, y_1 in terms of the original coordinates x, y . The formulae involve (a, b) , the original coordinates of the new origin; it would be easy instead of these to introduce (a_1, b_1) , the new coordinates of the origin. Writing $(a, b) = (0, 0)$, we have, of course, the formulae for transformation between two sets of rectangular axes having the same origin, and it is as well to write the formulae in this more simple form; the subsequent transformation to a new origin, but with axes parallel to the original axes, can then be effected without any difficulty.

15. All questions in regard to the line may be solved by means of one or other of the foregoing forms—

$$\begin{aligned} Ax + By + C &= 0, \\ y &= Ax + B, \\ x - a &= \frac{y-b}{\sin \alpha}, \\ (x-a) \cos \alpha + (y-b) \sin \alpha &= p = 0; \end{aligned}$$

or it may be by a comparison of these different forms: thus, using the first form, it has been already shown that the equation of the line through two given points (x_1, y_1) , (x_2, y_2) is

$$x(y_1 - y_2) - y(x_1 - x_2) + x_1 y_2 - x_2 y_1 = 0,$$

or, as this may be written,

$$y - y_1 = \frac{y_2 - y_1}{x_2 - x_1} (x - x_1)$$

A particular case is the equation

$$\frac{x}{a} + \frac{y}{b} = 1,$$

representing the line through the points $(a, 0)$ and $(0, b)$, or, what is the same thing, the line meeting the axes of x and y at the distances from the origin a and b respectively. It may be noticed that, in the form $Ax + By + C = 0$, $-\frac{A}{B}$

denotes the tangent of the inclination to the axis of x , or we may say that $B - \sqrt{A^2 + B^2}$ and $A - \sqrt{A^2 + B^2}$ denote respectively the cosine and the sine of the inclination to the axis of x . A better form is this: $A - \sqrt{A^2 + B^2}$ and $B - \sqrt{A^2 + B^2}$ denote respectively the cosine and the sine of inclination to the axis of x of the perpendicular upon the line. So of course, in regard to the form $y = Ax + B$, A is here the tangent of the inclination to the axis of x ; $1 + \sqrt{A^2 + 1}$ and $A - \sqrt{A^2 + 1}$ are the cosine and sine of this inclination, &c. It thus appears that the condition in order that the lines $Ax + By + C = 0$ and $A'x + B'y + C' = 0$ may meet at right angles is $AA' + BB' = 0$; so when the equations are $y = Ax + B$, $y = A'x + B'$, the condition is $AA' + 1 = 0$, or say the value of A' is $= -1/A$.

The perpendicular distance of the point (a, b) from the line $Ax + By + C = 0$ is $(Aa + Bb + C) / \sqrt{A^2 + B^2}$. In all the formulae involving $\sqrt{A^2 + B^2}$ or $\sqrt{A^2 + 1}$, the radical should be written with the sign \pm , which is essentially indeterminate: the like indeterminateness of sign presents itself in the expression for the distance of two points $p = \pm \sqrt{(x-a)^2 + (y-b)^2}$; if, as before, the points are Q, P , and the indefinite line through these is $Q'Pz$, then it is the same thing whether we measure off from Q along this line, considered as drawn from z' towards z , a positive

distance h , or along the line considered as drawn reversely from z towards z' , the equal negative distance $-h$, and the expression for the distance ρ is thus properly of the form $\pm h$. It is interesting to compare expressions which do not involve a radical. thus, in seeking for the expression for the perpendicular distance of the point (a, b) from a given line, let the equation of the given line be taken in the form, $x \cos \alpha + y \sin \alpha - p = 0$ (p being the perpendicular distance from the origin, α its inclination to the axis of x): the equation of the line may also be written $(x-a) \cos \alpha + (y-b) \sin \alpha - p_1 = 0$, and we have thence $p_1 = p - a \cos \alpha - b \sin \alpha$, the required expression for the distance p_1 . it is here assumed that p_1 is drawn from (a, b) in the same sense as p is drawn from the origin, and the indeterminateness of sign is thus removed.

16. As an instance of the mode of using the formulæ, take the problem of finding the locus of a point such that its distance from a given point is in a given ratio to its distance from a given line.

We take (a, b) as the coordinates of the given point, and it is convenient to take (x, y) as the coordinates of the variable point, the locus of which is required: it thus becomes necessary to use other letters, say (X, Y) , for current coordinates in the equation of the given line. Suppose this is a line such that its perpendicular distance from the origin is $=p$, and that the inclination of p to the axis of x is $=\alpha$; the equation is $X \cos \alpha + Y \sin \alpha - p = 0$. In the result obtained in § 15, writing (x, y) in place of (a, b) , it appears that the perpendicular distance of this line from the point (x, y) is

$$= p - x \cos \alpha - y \sin \alpha,$$

hence the equation of the locus is

$$\sqrt{(x-a)^2 + (y-b)^2} = e(p - x \cos \alpha - y \sin \alpha),$$

or say

$$(x-a)^2 + (y-b)^2 - e^2(x \cos \alpha + y \sin \alpha - p)^2 = 0,$$

an equation of the second order.

The Conics (Parabola, Ellipse, Hyperbola).

17 The conics or, as they were called, conic sections were originally defined as the sections of a right circular cone; but Apollonius substituted a definition, which is in fact that of the last example: the curve is the locus of a point such that its distance from a given point (called the focus) is in a given ratio to its distance from a given line (called the directrix); taking the ratio as $e:1$, then e is called the eccentricity.

Take FD for the perpendicular from the focus F upon the directrix, and the given ratio being that of $e:1$ ($e > 1$, or < 1 , but positive), and let the distance FD be divided at O in the given ratio, say we have $OD = m$, $OF = em$, where m is positive;—then the origin may be taken at O, the axis Ox being in the direction OF (that is from O to F), and the axis Oy at right angles to it. The distance of the point (x, y) from F is $=\sqrt{(x-em)^2 + y^2}$, its distance from the directrix is $=x+m$; the equation therefore is

$$(x-em)^2 + y^2 = e^2(x+m)^2,$$

or, what is the same thing, it is

$$(1-e^2)x^2 - 2me(1+e)x + y^2 = 0.$$

If $e^2=1$, or, since e is taken to be positive, if $e=1$, this is which is the parabola.

If $e^2 \text{ not } = 1$, then the equation may be written

$$(1-e^2)\left(x - \frac{me}{1-e^2}\right) + y^2 = \frac{m^2e^2(1+e)}{1-e^2}.$$

Supposing e positive and < 1 , then, writing $m = \frac{a(1-e)}{e}$, the equation becomes

$$(1-e^2)(x-a)^2 + y^2 = a^2(1-e^2),$$

that is,

$$\frac{(x-a)^2}{a^2} + \frac{y^2}{a^2(1-e^2)} = 1;$$

or, changing the origin and writing $b^2 = a^2(1-e^2)$, this is

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1,$$

which is the ellipse

And similarly if e be positive and > 1 , then writing $m = \frac{a(e-1)}{e}$, the equation becomes

$$(1-e^2)(x+a)^2 + y^2 = a^2(1-e^2),$$

that is,

$$\frac{(x+a)^2}{a^2} + \frac{y^2}{a^2(1-e^2)} = 1,$$

or changing the origin and writing $b^2 = a^2(e^2-1)$, this is

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1,$$

which is the hyperbola.

18. The general equation $ax^2 + 2hxy + by^2 + 2fx + c = 0$, or as it is written $(a, b, c, f, g, h)(x, y, 1)^2 = 0$, may be such that the quadric function breaks up into factors, $= (ax + \beta y + \gamma)(\alpha x + \beta' y + \gamma')$; and in this case the equation represents a pair of lines, or (it may be) two coincident lines. When it does not so break up, the function can be put in the form $\lambda\{(x-a')^2 + (y-b')^2 - e^2(a \cos \alpha + y \sin \alpha - p)^2\}$, or, equating the two expressions there will be six equations for the determination of $\lambda, a', b', e, p, \alpha$; and by what precedes, if a', b', e, p, α are real, the curve is either a parabola, ellipse, or hyperbola. The original coefficients (a, b, c, f, g, h) may be such as not to give any system of real values for a', b', e, p, α , but when this is so the equation $(a, b, c, f, g, h)(x, y, 1)^2 = 0$ does not represent a real curve; the imaginary curve which it represents is, however, regarded as a conic. Disregarding the special cases of the pair of lines and the twice repeated line, it thus appears that the only real curves represented by the general equation $(a, b, c, f, g, h)(x, y, 1)^2 = 0$ are the parabola, the ellipse, and the hyperbola. The circle is considered as a particular case of the ellipse.

The same result is obtained by transforming the equation $(a, b, c, f, g, h)(x, y, 1)^2 = 0$ to new axes. If in the first place the origin be unaltered, then the directions of the new (rectangular) axes Ox_1, Oy_1 can be found so that h_1 (the coefficient of the term x_1y_1) shall be $= 0$; when this is done, then either one of the coefficients of a_1^2, y_1^2 is $= 0$, and the curve is then a parabola, or neither of these coefficients is $= 0$, and the curve is then an ellipse or hyperbola, according as the two coefficients are of the same sign or of opposite signs.

19. The curves can be at once traced from their equations:—

$$y^2 = 4mx, \text{ for the parabola (fig. 13),}$$

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1, \text{ for the ellipse (fig. 14),}$$

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1, \text{ for the hyperbola (fig. 15);}$$

and it will be noticed how the form of the last equation puts in evidence the two asymptotes $\frac{y}{a} = \pm \frac{y}{b}$ of the hyperbola. Referred to the asymptotes (as a set of

¹ It is proper to remark that when $(a, b, c, f, g, h)(x, y, 1)^2 = 0$ does represent a real curve, there are in fact four systems of values of a', b', e, p, α , a two real, the other two imaginary, we have thus two real equations and two imaginary equations, each of them of the form $(x-a')^2 + (y-b')^2 - e^2(\cos \alpha + y \sin \alpha - p)^2$, representing each of them the one and the same real curve. This is consistent with the assertion of the text that the real curve is in every case represented by a real equation of this form.

Fig. 12.

oblique axes) the equation of the hyperbola takes the form $xy=c$; and in particular, if in this equation the

Fig. 13.

Fig. 14.

Fig. 15

axes are at right angles, then the equation represents the rectangular hyperbola referred to its asymptotes as axes.

Tangent, Normal, Circle and Radius of Curvature, &c.

20. There is great convenience in using the language and notation of the infinitesimal analysis; thus we consider on a curve a point with coordinates (x, y) , and a consecutive point the coordinates of which are $(x+dx, y+dy)$, or again a second consecutive point with coordinates $(x+dx+\frac{1}{2}d^2x, y+dy+\frac{1}{2}d^2y)$, &c.; and in the final results the ratios of the infinitesimals must be replaced by differential coefficients in the proper manner, thus, if x, y are considered as given functions of a parameter θ , then dx, dy have in fact the values $\frac{dx}{d\theta}d\theta, \frac{dy}{d\theta}d\theta$, and (only the ratio being really material) they may in the result be replaced by $\frac{dx}{d\theta}, \frac{dy}{d\theta}$. This includes the case where the equation of the curve is given in the form $y=\phi(x)$; θ is here $=x$, and the increments dx, dy are in the result to be replaced by 1, $\frac{dy}{dx}$. So also with the infinitesimals of the higher orders d^2x, d^2y , &c.

21. The tangent at the point (x, y) is the line through this point and the consecutive point $(x+dx, y+dy)$; hence, taking ξ, η as current coordinates, the equation is

$$\frac{\xi-x}{dx} = \frac{\eta-y}{dy},$$

an equation which is satisfied on writing therein $\xi, \eta = (x, y)$ or $= (x+dx, y+dy)$. The equation may be written

$$\eta - y = \frac{dy}{dx}(\xi - x),$$

$\frac{dy}{dx}$ being now the differential coefficient of y in regard to x ; and this form is applicable whether y is given directly as a function of x , or in whatever way y is in effect given as a function of x : if as before x, y are given each of them as a function of θ , then the value of $\frac{dy}{dx}$ is $= \frac{\frac{dy}{d\theta}}{\frac{dx}{d\theta}} = \frac{dy}{d\theta} \div \frac{dx}{d\theta}$, which is the result obtained from the original form on writing therein $\frac{dx}{d\theta}, \frac{dy}{d\theta}$ for dx, dy respectively.

So again, when the curve is given by an equation $u=0$ between the coordinates (x, y) , then $\frac{dy}{dx}$ is obtained from

the equation $\frac{du}{dx} + \frac{du}{dy} \frac{dy}{dx} = 0$. But here it is more elegant, using the original form, to eliminate dx, dy by the formula $\frac{du}{dx} dx + \frac{du}{dy} dy$; we thus obtain the equation of the tangent in the form

$$\frac{du}{dx}(\xi - x) + \frac{du}{dy}(\eta - y) = 0$$

For example, in the case of the ellipse $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$, the equation is $\frac{x}{a^2}(\xi - x) + \frac{y}{b^2}(\eta - y) = 0$; or reducing by means of the equation of the curve the equation of the tangent is

$$\frac{\xi x}{a^2} + \frac{\eta y}{b^2} = 1.$$

The normal is a line through the point at right angles to the tangent; the equation therefore is

$$(\xi - x)dx + (\eta - y)dy = 0,$$

where dx, dy are to be replaced by their proportional values as before.

22. The circle of curvature is the circle through the point and two consecutive points of the curve. Taking the equation to be

$$(\xi - a)^2 + (\eta - b)^2 = r^2,$$

the values of a, b are given by

$$a - a = \frac{dy(dx^2 + dy^2)}{dx^2y - dydx^2}, \quad b - b = \frac{-dx(dx^2 + dy^2)}{dx^2y - dydx^2},$$

and we then have

$$r^2 = (x-a)^2 + (y-b)^2 = \frac{(dx^2 + dy^2)^3}{(dx^2y - dydx^2)^2}$$

In the case where y is given directly as a function of x ,

then, writing for shortness $p = \frac{dy}{dx}$, $q = \frac{d^2y}{dx^2}$, this is

$$r^2 = \frac{(1+p^2)^3}{q^2}, \text{ or, as the equation is usually written,}$$

$r = \frac{(1+p^2)^{3/2}}{-q}$, the radius of curvature, considered to be positive or negative according as the curve is concave or convex to the axis of x .

It may be added that the centre of curvature is the intersection of the normal by the consecutive normal.

The locus of the centre of curvature is the evolute. If from the expressions of a, b regarded as functions of x we eliminate x , we have thus an equation between (a, b) , which is the equation of the evolute.

Polar Coordinates.

23. The position of a point may be determined by means of its distance from a fixed point and the inclination of this distance to a fixed line through the fixed point. Say we have r the distance from the origin, and θ the inclination of r to the axis of x ; r and θ are then the polar coordinates of the point, r the radius vector, and θ the inclination. These are immediately connected with the Cartesian coordinates x, y by the formulae $x = r \cos \theta$, $y = r \sin \theta$; and the transition from either set of coordinates to the other can thus be made without difficulty. But the use of polar coordinates is very convenient, as well in reference to certain classes of questions relating to curves of any kind—for instance, in the dynamics of central forces—as in relation to curves having in regard to the origin the symmetry of the regular polygon (curves such as that represented by the equation $r = \cos m\theta$), and also in regard to the class of curves called spirals, where

the radius vector r is given as an algebraical or exponential function of the inclination θ .

Trilinear Coordinates

24. Consider a fixed triangle ABC, and (regarding the sides as indefinite lines) suppose for a moment that p, q, r denote the distances of a point P from the sides BC, CA, AB respectively,—these distances being measured either perpendicularly to the several sides, or each of them in a given direction. To fix the ideas each distance may be considered as positive for a point inside the triangle, and the sign is thus fixed for any point whatever. There is then an identical relation between p, q, r . if a, b, c are the lengths of the sides, and the distances are measured perpendicularly thereto, the relation is $ap + bq + cr = 2$ times the area of triangle. But taking x, y, z proportional to p, q, r , or if we please proportional to given multiples of p, q, r , then only the ratios of x, y, z are determined; their absolute values remain arbitrary. But the ratios of p, q, r , and consequently also the ratios of x, y, z determine, and that uniquely, the point, and it being understood that only the ratios are attended to, we say that (x, y, z) are the coordinates of the point. The equation of a line has thus the form $ax + by + cz = 0$, and generally that of a curve of the n th order is a homogeneous equation of this order between the coordinates, $(x, y, z)^n = 0$. The advantage over Cartesian coordinates is in the greater symmetry of the analytical forms, and in the more convenient treatment of the line infinity and of points at infinity. The method includes that of Cartesian coordinates, the homogeneous equation in x, y, z is in fact an equation in $\frac{x}{z}, \frac{y}{z}$, which two quantities may be regarded as denoting Cartesian coordinates; or, what is the same thing, we may in the equation write $z = 1$. It may be added that if the trilinear coordinates (x, y, z) are regarded as the Cartesian coordinates of a point of space, then the equation is that of a cone having the origin for its vertex; and conversely that such equation of a cone may be regarded as the equation in trilinear coordinates of a plane curve

General Point-Coordinates.—Line-Coordinates.

25. All the coordinates considered thus far are point-coordinates. More generally, any two quantities (or the ratios of three quantities) serving to determine the position of a point in the plane may be regarded as the coordinates of the point; or, if instead of a single point they determine a system of two or more points, then as the coordinates of the system of points. But, as noticed under CURVES, there are also line-coordinates serving to determine the position of a line; the ordinary case is when the line is determined by means of the ratios of three quantities ξ, η, ζ (correlative to the trilinear coordinates x, y, z). A linear equation $a\xi + b\eta + c\zeta = 0$ represents then the system of lines such that the coordinates of each of them satisfy this relation, in fact, all the lines which pass through a given point; and it is thus regarded as the line-equation of this point; and generally a homogeneous equation $(\xi, \eta, \zeta)^n = 0$ represents the curve which is the envelope of all the lines the coordinates of which satisfy this equation, and it is thus regarded as the line-equation of this curve.

II. SOLID ANALYTICAL GEOMETRY (§§26–40).

26. We are here concerned with points in space,—the position of a point being determined by its three coordinates x, y, z . We consider three coordinate planes, at right angles to each other, dividing the whole of space into eight portions called octants, the coordinates of a point being the perpendicular distances of the point from

the three planes respectively, each distance being considered as positive or negative according as it lies on the one or the other side of the plane. Thus the coordinates in the eight octants have respectively the signs

Fig. 16.

The positive parts of the axes are usually drawn as in fig. 16, which represents a point P, the coordinates of which have the positive values OM, MN, NP.

27. It may be remarked, as regards the delineation of such solid figures, that if we have in space three lines at right angles to each other, say Oa, Ob, Oc , of equal lengths, then it is possible to project these by parallel lines upon a plane in such wise that the projections Oa', Ob', Oc' shall be at given inclinations to each other, and that these lengths shall be to each other in given ratios: in particular the two lines Oa', Oc' may be at right angles to each other, and their lengths equal, the direction of Ob' , and its proportion to the two equal lengths Oa', Oc' being arbitrary. It thus appears that we may as in the figure draw Ox, Oy at right angles to each other, and Oy in an arbitrary direction; and moreover represent the coordinates x, z on equal scales, and the remaining coordinate y on an arbitrary scale (which may be that of the other two coordinates x, z , but is in practice usually smaller). The advantage, of course, is that a figure in one of the coordinate planes xy is represented in its proper form without distortion; but it may be in some cases preferable to employ the isometrical projection, wherein the three axes are represented by lines inclined to each other at angles of 120° , and the scales for the coordinates are equal (fig. 17).

For the delineation of a surface of a tolerably simple form, it is frequently sufficient to draw (according to the foregoing projection) the sections by the coordinate planes; and in particular when the surface is symmetrical in regard to the coordinate planes, it is sufficient to draw the quarter-sections belonging to a single octant of the surface; thus fig. 18 is a convenient representation of an octant of the wave surface. Or a surface may be delineated by means of a series of parallel sections, or (taking these to be the sections by a series of horizontal planes) say by a series of contour lines. Of course, other sections may be drawn or indicated, if necessary. For the delineation of a curve, a convenient method is to represent, as above, a series of the points P thereof, each point P being accompanied by the ordinates PN, which serves to refer the point to the plane of xy ; this is in effect a representation of each point P of the curve, by means of two points P, N such that the line PN has a fixed direction. Both as regards curves and surfaces, the employment of stereographic representations is very interesting.

Fig. 17.

Fig. 18: A 3D coordinate system with axes x, y, and z. The origin is labeled O. A point P is shown in the first octant. Its projections onto the axes are labeled M on the x-axis, N on the y-axis, and P on the z-axis. The axes are shown at 120-degree angles to each other.

28. In plane geometry, reckoning the line as a curve of the first order, we have only the point and the curve. In solid geometry, reckoning a line as a curve of the first order, and the plane as a surface of the first order, we

Fig. 18

have the point, the curve, and the surface; but the increase of complexity is far greater than would hence at first sight appear. In plane geometry a curve is considered in connexion with lines (its tangents), but in solid geometry the curve is considered in connexion with lines and planes (its tangents and osculating planes), and the surface also in connexion with lines and planes (its tangent lines and tangent planes); there are surfaces arising out of the line—cones, skew surfaces, developables, doubly and triply infinite systems of lines, and whole classes of theories which have nothing analogous to them in plane geometry: it is thus a very small part indeed of the subject which can be even referred to in the present article.

In the case of a surface we have between the coordinates (x, y, z) a single, or say a onefold relation, which can be represented by a single relation $f(x, y, z) = 0$, or we may consider the coordinates expressed each of them as a given function of two variable parameters p, q ; the form $z = f(x, y)$ is a particular case of each of these modes of representation; in other words, we have in the first mode $f(x, y, z) = z - f(x, y)$, and in the second mode $x = p, y = q$ for the expression of two of the coordinates in terms of the parameters.

In the case of a curve we have between the coordinates (x, y, z) a twofold relation: two equations $f(x, y, z) = 0, \phi(x, y, z) = 0$ give such a relation; i.e., the curve is here considered as the intersection of two surfaces (but the curve is not always the complete intersection of two surfaces, and there are hence difficulties); or, again, the coordinates may be given each of them as a function of a single variable parameter. The form $y = \phi x, z = \psi x$, where two of the coordinates are given in terms of the third, is a particular case of each of these modes of representation.

29. The remarks under plane geometry as to descriptive and metrical propositions, and as to the non-metrical character of the method of coordinates when used for the proof of a descriptive proposition, apply also to solid geometry; and they might be illustrated in like manner by the instance of the theorem of the radical centre of four spheres. The proof is obtained from the consideration that S and S' being each of them a function of the form $ax^2 + y^2 + z^2 + cx + dy + ez + d$, the difference $S - S'$ is a mere linear function of the coordinates, and consequently that $S - S' = 0$ is the equation of the plane containing the circle of intersection of the two spheres $S = 0$ and $S' = 0$.

Metrical Theory.

30. The foundation in solid geometry of the metrical theory is in fact the before-mentioned theorem that if a

finite right line PQ be projected upon any other line OO' by lines perpendicular to OO' , then the length of the projection $P'Q'$ is equal to the length of PQ into the cosine of its inclination to $P'Q'$ —or (in the form in which it is now convenient to state the theorem) the perpendicular distance $P'Q'$ of two parallel planes is equal to the inclined distance PQ into the cosine of the inclination. Hence also the algebraical sum of the projections of the sides of a closed polygon upon any line is $= 0$; or, reversing the signs of certain sides and considering the polygon as made up of two broken lines each extending from the same initial to the same terminal point, the sum of the projections of the one set of lines upon any line is equal to the sum of the projections of the other set of lines upon the same line. When any of the lines are at right angles to the given line (or, what is the same thing, in a plane at right angles to the given line) the projections of these lines severally vanish.

31. Consider the skew quadrilateral $QMNP$, the sides QM, MN, NP being respectively parallel to the three rectangular axes Ox, Oy, Oz , let the lengths of these sides be ξ, η, ζ , and that of the side QP be ρ ; and let the cosines of the inclinations (or say the cosine-inclinations) of ρ to the three axes be α, β, γ ; then projecting successively on the three sides and on QP we have

$$\xi, \eta, \zeta = \rho\alpha, \rho\beta, \rho\gamma,$$

and

$$\rho = \alpha\xi + \beta\eta + \gamma\zeta,$$

whence $\rho^2 = \xi^2 + \eta^2 + \zeta^2$, which is the relation between a distance ρ and its projections ξ, η, ζ upon three rectangular axes. And from the same equations we obtain $\alpha^2 + \beta^2 + \gamma^2 = 1$, which is a relation connecting the cosine-inclinations of a line to three rectangular axes.

Suppose we have through Q any other line QT , and let the cosine-inclinations of this to the axes be α', β', γ' , and δ be its cosine-inclination to QP , also let p be the length of the projection of QP upon QT ; then projecting on QT we have

$$p = \alpha\xi + \beta\eta + \gamma\zeta, \quad p\delta$$

And in the last equation substituting for ξ, η, ζ their values $\rho\alpha, \rho\beta, \rho\gamma$ we find

$$\delta = \alpha\alpha' + \beta\beta' + \gamma\gamma',$$

which is an expression for the mutual cosine-inclination of two lines, the cosine-inclinations of which to the axes are α, β, γ and α', β', γ' respectively. We have of course $\alpha^2 + \beta^2 + \gamma^2 = 1$, and $\alpha'^2 + \beta'^2 + \gamma'^2 = 1$, and hence also

$$1 - \delta^2 = \alpha^2 + \beta^2 + \gamma^2 (\alpha'^2 + \beta'^2 + \gamma'^2) - (\alpha\alpha' + \beta\beta' + \gamma\gamma')^2 \\ = (\beta\gamma' - \beta'\gamma)^2 + (\gamma\alpha' - \gamma'\alpha)^2 + (\alpha\beta' - \alpha'\beta)^2;$$

so that the sine of the inclination can only be expressed as a square root. These formulae are the foundation of spherical trigonometry.

The Line, Plane, and Sphere.

32. The foregoing formulae give at once the equations of these loci.

For first, taking Q to be a fixed point, coordinates (a, b, c) and the cosine-inclinations (α, β, γ) to be constant, then P will be a point in the line through Q in the direction thus determined; or, taking (x, y, z) for its coordinates, these will be the current coordinates of a point in the line. The values of ξ, η, ζ then are $x - a, y - b, z - c$, and we thus have

$$\frac{x-a}{\alpha} = \frac{y-b}{\beta} = \frac{z-c}{\gamma} = \rho,$$

which (omitting the last equation, $= \rho$) are the equations of the line through the point (a, b, c) , the cosine-inclinations to the axes being α, β, γ , and these quantities being connected by the relation $\alpha^2 + \beta^2 + \gamma^2 = 1$. This equation may be omitted, and then α, β, γ , instead of being equal, will only be proportional to the cosine-inclinations.

Using the last equation, and writing

$$ax, y, z = \alpha + \alpha\rho, \beta + \beta\rho, c + \gamma\rho,$$

these are expressions for the current coordinates in terms of a parameter ρ , which is in fact the distance from the fixed point (a, b, c) .

It is easy to see that, if the coordinates (x, y, z) are connected by any two linear equations, these equations can always be brought

into the foregoing form, and hence that the two linear equations represent a line

Secondly, taking for greater simplicity the point Q to be coincident with the origin, and $\alpha', \beta', \gamma', p$ to be constant, then p is the perpendicular distance of a plane from the origin, and α', β', γ' are the cosine-inclinations of this distance to the axes ($\alpha'^2 + \beta'^2 + \gamma'^2 = 1$). P is any point in this plane, and taking its coordinates to be (x, y, z) then (ξ, η, ζ) are $-(x, y, z)$, and the foregoing equation $p = \alpha'\xi + \beta'\eta + \gamma'\zeta$ becomes

$$\alpha'(x - \alpha) + \beta'(y - b) + \gamma'(z - c) = p,$$

which is the equation of the plane in question

If, more generally, Q is not coincident with the origin, then, taking its coordinates to be (u, b, c) , and writing p_1 instead of p , the equation is

$$\alpha'(x - \alpha) + \beta'(y - b) + \gamma'(z - c) = p_1,$$

and we thence have $p_1 = p - (\alpha\alpha' + b\beta' + c\gamma')$, which is an expression for the perpendicular distance of the point (α, b, c) from the plane in question.

It is obvious that any linear equation $Ax + By + Cz + D = 0$ between the coordinates can always be brought into the foregoing form, and hence that such equation represents a plane.

Thirdly, supposing Q to be a fixed point, coordinates (α, b, c) and the distance $QF = p$, to be constant, say this is $\alpha = a$, then, as before, the values of ξ, η, ζ are $x - a, y - b, z - c$, and the equation $\xi^2 + \eta^2 + \zeta^2 = \rho^2$ becomes

$$(x - a)^2 + (y - b)^2 + (z - c)^2 = \rho^2,$$

which is the equation of the sphere, coordinates of the centre $= (\alpha, b, c)$ and radius $= d$.

A quadratic equation whetein the terms of the second order are $x^2 + y^2 + z^2$, viz., an equation

$$x^2 + y^2 + z^2 + Ax + By + Cz + D = 0,$$

can always, it is clear, be brought into the foregoing form; and it thus appears that this is the equation of a sphere, coordinates of the centre $= \frac{1}{2}A, -\frac{1}{2}B, -\frac{1}{2}C$, and squared radius $= \frac{1}{4}(A^2 + B^2 + C^2) - D$.

Cylinders, Cones, Ruled Surfaces.

33. A singly infinite system of lines or system of lines depending upon one variable parameter forms a surface; and the equation of the surface is obtained by eliminating the parameter between the two equations of the line.

If the lines all pass through a given point, then the surface is a cone; and, in particular, if the lines are all parallel to a given line, then the surface is a cylinder.

Beginning with this last case, suppose the lines are parallel to the line $x = mz, y = nz$, the equations of a line of the system are $x = mz + a, y = nz + b$, where a, b are supposed to be functions of the variable parameter, or, what is the same thing, there is between them a relation $f(a, b) = 0$: we have $a = z - mz, b = y - nz$, and the result of the elimination of the parameter therefore is $f(y - nz, z - mz) = 0$, which is thus the general equation of the cylinder the generating lines whereof are parallel to the line $x = mz, y = nz$. The equation of the section by the plane $z = 0$ is $f(y, y) = 0$, and conversely if the cylinder be determined by means of its curve of intersection with the plane $z = 0$, then, taking the equation of this curve to be $f(x, y) = 0$, the equation of the cylinder is $f(x - mz, y - nz) = 0$. Thus, if the curve of intersection be the circle $(x - a)^2 + (y - b)^2 = r^2$, we have $(x - mz - a)^2 + (y - nz - b)^2 = r^2$ as the equation of an oblique cylinder on this base, and thus also $(x - a)^2 + (y - b)^2 = r^2$ as the equation of the right cylinder.

If the lines all pass through a given point (α, b, c) , then the equations of a line are $x - \alpha = a(z - c), y - b = \beta(z - c)$, where a, β are functions of the variable parameter, or, what is the same thing, there exists between them an equation $f(a, \beta) = 0$; the elimination of the parameter gives, therefore, $f\left(\frac{x - \alpha}{z - c}, \frac{y - b}{z - c}\right) = 0$, and this equation, or, what is the same thing, any homogeneous equation $f(z - \alpha, y - b, z - c) = 0$, or, taking f to be a rational and integral function of the order n , say $f(z - \alpha, y - b, z - c) = 0$, is the general equation of the cone having the point (α, b, c) for its vertex. Taking the vertex to be at the origin, the equation is $f(x, y, z) = 0$ and, in particular, $f(x, y, z) = 0$ is the equation of a cone of the second order, or quadricone, having the origin for its vertex.

34. In the general case of a singly infinite system of lines, the locus is a ruled surface (or *regulus*). If the system be such that a line does not intersect the consecutive line, then the surface is a skew surface, or scroll; but if it be such that each line intersects the consecutive line, then it is a developable, or torse.

Suppose, for instance, that the equations of a line (depending on the variable parameter θ) are $\frac{x}{a} + \frac{y}{c} = \theta\left(1 + \frac{y}{b}\right), \frac{z}{a} - \frac{z}{c} = \frac{1}{\theta}\left(1 - \frac{y}{b}\right)$,

then, eliminating θ , we have $\frac{x^2}{a^2} - \frac{z^2}{c^2} = 1 - \frac{y^2}{b^2}$, or say $\frac{x^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1$, the equation of a quadric surface, afterwards called the hyperboloid of one sheet, this surface is consequently a scroll. It is to be remarked that we have upon the surface a second singly infinite series of lines; the equations of a line of this second system (depending on the variable parameter ϕ) are

$$\frac{x}{a} + \frac{z}{c} = \phi\left(1 - \frac{y}{b}\right), \frac{x}{a} - \frac{z}{c} = \frac{1}{\phi}\left(1 + \frac{y}{b}\right).$$

It is easily shown that any line of the one system intersects every line of the other system.

Considering any curve (of double curvature) whatever, the tangent lines of the curve form a singly infinite system of lines, each line intersecting the consecutive line of the system—that is, they form a developable, or torse, the curve and torse are thus inseparably connected together, forming a single geometrical figure. A plane through three consecutive points of the curve (or osculating plane of the curve) contains two consecutive tangents, that is, two consecutive lines of the torse, and is thus a tangent plane of the torse along a generating line.

Transformation of Coordinates.

35. There is no difficulty in changing the origin, and it is for brevity assumed that the origin remains unaltered. We have, then, two sets of rectangular axes, Ox, Oy, Oz , and Ox_1, Oy_1, Oz_1 , the mutual cosine-inclinations being shown by the diagram—

	x	y	z
x_1	α	β	γ
y_1	α'	β'	γ'
z_1	α''	β''	γ''

that is, α, β, γ are the cosine-inclinations of Ox_1 to Ox, Oy, Oz ; α', β', γ' those of Oy_1 , &c.

And this diagram gives also the linear expressions of the coordinates (x_1, y_1, z_1) or (x, y, z) of either set in terms of those of the other set, we thus have

$$\begin{aligned} x_1 &= \alpha x + \beta y + \gamma z, & x &= \alpha x_1 + \alpha' y_1 + \alpha'' z_1, \\ y_1 &= \alpha' x + \beta' y + \gamma' z, & y &= \beta x_1 + \beta' y_1 + \beta'' z_1, \\ z_1 &= \alpha'' x + \beta'' y + \gamma'' z, & z &= \gamma x_1 + \gamma' y_1 + \gamma'' z_1, \end{aligned}$$

which are obtained by projection, as above explained. Each of these equations is, in fact, nothing else than the before-mentioned equation $p = \alpha'\xi + \beta'\eta + \gamma'\zeta$, adapted to the problem in hand.

But we have to consider the relations between the nine coefficients. By what precedes, or by the consideration that we must have identically $x^2 + y^2 + z^2 = x_1^2 + y_1^2 + z_1^2$, it appears that these satisfy the relations—

$$\begin{aligned} \alpha^2 + \beta^2 + \gamma^2 &= 1, & \alpha'^2 + \alpha''^2 + \alpha'''^2 &= 1, \\ \alpha\alpha' + \beta\beta' + \gamma\gamma' &= 0, & \beta\beta' + \beta\beta'' + \beta\beta''' &= 0, \\ \alpha\alpha'' + \beta\beta'' + \gamma\gamma'' &= 0, & \gamma\gamma' + \gamma\gamma'' + \gamma\gamma''' &= 0, \\ \alpha\alpha' + \beta\beta' + \gamma\gamma' &= 0, & \gamma\gamma' + \gamma\gamma'' + \gamma\gamma''' &= 0, \\ \alpha\alpha'' + \beta\beta'' + \gamma\gamma'' &= 0, & \alpha\beta + \alpha\beta' + \alpha\beta'' &= 0, \\ \alpha\alpha' + \beta\beta' + \gamma\gamma' &= 0, & \alpha\beta + \alpha\beta' + \alpha\beta'' &= 0, \end{aligned}$$

either set of six equations being implied in the other set.

It follows that the square of the determinant

$$\begin{vmatrix} \alpha & \beta & \gamma \\ \alpha' & \beta' & \gamma' \\ \alpha'' & \beta'' & \gamma'' \end{vmatrix}$$

is ± 1 , and hence that the determinant itself is ± 1 . The distinction of the two cases is an important one. If the determinant is $+1$, then the axes Ox_1, Oy_1, Oz_1 are such that they can by a rotation about O be brought to coincide with Ox, Oy, Oz respectively; if it is -1 , then they cannot. But in the latter case, by measuring x_1, y_1, z_1 in the opposite directions we change the signs of all the coefficients and so make the determinant to be $+1$; hence this case need alone be considered, and it is accordingly assumed that the determinant is $+1$. This being so, it is found that we have a further set of nine equations, $\alpha = \beta'\gamma' - \beta''\gamma''$, &c.; that is, the coefficients arranged as in the diagram have the values

$\beta'\gamma' - \beta''\gamma''$	$\gamma'\alpha' - \gamma''\alpha''$	$\alpha'\beta' - \alpha''\beta''$
$\beta''\gamma'' - \beta'\gamma'$	$\gamma''\alpha'' - \gamma'\alpha'$	$\alpha''\beta'' - \alpha'\beta'$
$\beta'\gamma' - \beta''\gamma''$	$\gamma\alpha' - \gamma'\alpha''$	$\alpha\beta' - \alpha'\beta''$

36. It is important to express the nine coefficients in terms of three independent quantities. A solution which, although unsymmetrical, is very convenient in Astronomy and Dynamics is to say for the purpose the three angles θ , ϕ , τ of fig. 19; say θ = longitude of the node, ϕ = inclination and τ = longitude of x_1 from node.

Fig. 19.

The diagram of transformation then is

	x	y	z
x_1	$\cos \tau \cos \theta - \sin \tau \sin \theta \cos \phi$	$\cos \tau \sin \theta + \sin \tau \cos \theta \cos \phi$	$\sin \tau \sin \phi$
y_1	$-\sin \tau \cos \theta - \cos \tau \sin \theta \cos \phi$	$-\sin \tau \sin \theta + \cos \tau \cos \theta \cos \phi$	$\cos \tau \sin \phi$
z_1	$\sin \theta \sin \phi$	$-\cos \theta \sin \phi$	$\cos \phi$

But a more elegant solution (due to Rodrigues) is that contained in the diagram

	ω	y	z
x_1	$1 + \lambda^2 - \mu^2 - \nu^2$	$2(\lambda\mu - \nu)$	$2(\lambda\nu + \mu)$
y_1	$2(\lambda\mu + \nu)$	$1 - \lambda^2 + \mu^2 - \nu^2$	$2(\mu\nu - \lambda)$
z_1	$2(\nu\lambda - \mu)$	$2(\mu\nu + \lambda)$	$1 - \lambda^2 - \mu^2 + \nu^2$

$$+ (1 + \lambda^2 - \mu^2 + \nu^2)$$

The nine coefficients of transformation are the nine functions of the diagram, each divided by $1 + \lambda^2 + \mu^2 + \nu^2$; the expressions contain as they should do the three arbitrary quantities λ , μ , ν ; and the identity $x_1^2 + y_1^2 + z_1^2 = \omega^2 + y^2 + z^2$ can be at once verified. It may be added that the transformation can be expressed in the quaternion form

$$x_1 + jy_1 + kz_1 = (1 + \Lambda)(x + jy + kz)(1 + \Lambda)^{-1}$$

where Λ denotes the vector $\lambda i + \mu j + \nu k$.

Quadric Surfaces (Paraboloids, Ellipsoid, Hyperboloids).

37. It appears by a discussion of the general equation of the second order $(ax^2 + by^2 + cz^2 + 2dxy + 2exz + 2fyz) = 0$ that the proper quadric surfaces represented by such an equation are the following five surfaces (a and b positive):—

- (1.) $z = \frac{a^2}{2a} - \frac{y^2}{2b}$, elliptic paraboloid.
- (2.) $z = \frac{a^2}{2a} - \frac{y^2}{2b}$, hyperbolic paraboloid.
- (3.) $\frac{a^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1$, ellipsoid.
- (4.) $\frac{a^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1$, hyperboloid of one sheet.
- (5.) $\frac{a^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = -1$, hyperboloid of two sheets.

¹ The improper quadric surfaces represented by the general equation of the second order are (1) the pair of planes or plane-pair, including as a special case the twice repeated plane, and (2) the cone, including as a special case the cylinder. There is but one form of cone; but the cylinder may be parabolic, elliptic, or hyperbolic.

It is at once seen that these are distinct surfaces, and the equations also show very readily the general form and mode of generation of the several surfaces.

In the elliptic paraboloid (fig. 20), the sections by the planes of xz and xy are the parabolas

$$z = \frac{a^2}{2a} - \frac{y^2}{2b},$$

having the common axes Oz , and the section by any plane $z = \gamma$ parallel to that of xy is the ellipse

$$\gamma = \frac{a^2}{2a} + \frac{y^2}{2b},$$

so that the surface is generated by a variable ellipse moving parallel to itself along the parabolas as directrices.

In the hyperbolic paraboloid (fig. 21) the sections by the planes of xz , yz are the parabolas $z = \frac{a^2}{2a}$, $z = -\frac{a^2}{2b}$ hav-

ing the opposite axes Oz , Oz' , and the section by a plane $z = \gamma$ parallel to that of xy is the

hyperbola $\gamma = \frac{a^2}{2a} - \frac{y^2}{2b}$, which has its transverse axis parallel to Ox or Oy according as γ is positive or negative. The surface is thus generated by a variable hyperbola moving parallel to itself along the parabolas as directrices.

Fig. 20.

Fig. 21.

Fig. 22.

traces. The form is best seen from fig. 22, which represents the sections by planes parallel to the plane of xy , or say the contour lines, the continuous lines are the sections above the plane of xy , and the dotted lines the sections below this plane. The form is, in fact, that of a saddle.

In the ellipsoid (fig. 23) the sections by the planes of xz , yz , and xy are each of them an ellipse, and the section by any parallel plane is also an ellipse. The surface may be considered as generated by an ellipse moving parallel to itself along two ellipses as directrices.

In the hyperboloid of one sheet (fig. 24), the sections by the planes of xz , yz are the hyperbolas

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1, \quad \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1,$$

having a common conjugate axis Oz' ; the section by the plane of

Fig. 23.

xy , and that by any parallel plane, is an ellipse, and the surface may be considered as generated by a variable ellipse moving parallel to itself along the two hyperbolas as directrices

In the hyperboloid of two sheets (fig. 25), the sections by the planes of xz and xy are the hyperbolas

$$\frac{z^2}{c^2} - \frac{x^2}{a^2} = 1, \quad \frac{z^2}{c^2} - \frac{y^2}{b^2} = 1,$$

having the common transverse axis zOz' , the section by any plane $z = \pm \gamma$ parallel to that of xy , γ being in absolute magnitude $> c$, is the ellipse

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = \frac{\gamma^2}{c^2} - 1$$

and the surface, consisting of two distinct portions or sheets, may be considered as generated by a variable ellipse moving parallel to itself along the hyperbolas as directrices.

The hyperbolic paraboloid is such (and it is easy from the figure to understand how this may be the case) that there exist upon it two singly infinite series of right lines. The same is the case with the hyperboloid of one sheet (ruled or skew hyperboloid, as with reference to this property it is termed). If we imagine two equal and parallel circular disks, their points connected by strings of equal length, so that those on the generating lines of a right circular cylinder, then by turning one of the disks about its centre through the same angle in one or the other direction, the strings will in each case generate one and the same hyperboloid, and will in regard to it be the two systems of lines on the surface, or say the two systems of generating lines, and the general configuration is the same when instead of circles we have ellipses. It has been already shown analytically that the equation $\frac{x^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1$ is satisfied by each of two pairs of linear relations between the coordinates.

Curves, Tangent, Osculating Plane, Curvature, &c.

38. It will be convenient to consider the coordinates (x, y, z) of the point on the curve as given in terms of a parameter θ , so that $dx, dy, dz, d^2x, &c.$, will be proportional to $\frac{dx}{d\theta}, \frac{dy}{d\theta}, \frac{dz}{d\theta}, \frac{d^2x}{d\theta^2}, &c.$ But only a part of the analytical formulæ will be given. ξ, η, ζ are used as current coordinates.

The tangent is the line through the point (x, y, z) and the consecutive point $(x + dx, y + dy, z + dz)$; its equations therefore are

$$\frac{\xi - x}{dx} = \frac{\eta - y}{dy} = \frac{\zeta - z}{dz}.$$

The osculating plane is the plane through the point and two consecutive points, and contains therefore the tangent; its equation is

$$\begin{vmatrix} \xi - x & \eta - y & \zeta - z \\ \frac{dx}{d\theta} & \frac{dy}{d\theta} & \frac{dz}{d\theta} \\ \frac{d^2x}{d\theta^2} & \frac{d^2y}{d\theta^2} & \frac{d^2z}{d\theta^2} \end{vmatrix} = 0$$

or, what is the same thing,

$$(\xi - x)(dydz^2 - dzd^2y) + (\eta - y)(dzdx^2 - dx d^2z) + (\zeta - z)(dxd^2y - dy d^2x) = 0.$$

The normal plane is the plane through the point at right angles to the tangent. It meets the osculating plane in a line called the principal normal; and drawing through the point a line at right angles to the osculating plane, this is called the binormal. We have thus at the point a

set of three rectangular axes—the tangent, the principal normal, and the binormal.

We have through the point and three consecutive points a sphere of spherical curvature,—the centre and radius thereof being the centre, and radius, of spherical curvature. The sphere is met by the osculating plane in the circle of absolute curvature,—the centre and radius thereof being the centre, and radius, of absolute curvature. The centre of absolute curvature is also the intersection of the principal normal by the normal plane at the consecutive point.

Surfaces, Tangent Lines and Plane, Curvature, &c.

39. It will be convenient to consider the surface as given by an equation $f(x, y, z) = 0$ between the coordinates; taking (x, y, z) for the coordinates of a given point, and $(x + dx, y + dy, z + dz)$ for those of a consecutive point, the increments dx, dy, dz satisfy the condition

$$\frac{df}{dx} dx + \frac{df}{dy} dy + \frac{df}{dz} dz = 0,$$

but the ratio of two of the increments, suppose $dx : dy$, may be regarded as arbitrary. Only a part of the analytical formulæ will be given. ξ, η, ζ are used as current coordinates.

We have through the point a singly infinite series of right lines, each meeting the surface in a consecutive point, or say having each of them two-point intersection with the surface. These lines lie all of them in a plane which is the tangent plane; its equation is

$$\frac{df}{dx}(\xi - x) + \frac{df}{dy}(\eta - y) + \frac{df}{dz}(\zeta - z) = 0,$$

as is at once verified by observing that this equation is satisfied (irrespective of the value of $dx : dy$) on writing therein $\xi, \eta, \zeta = x + dx, y + dy, z + dz$.

The line through the point at right angles to the tangent plane is called the normal; its equations are

$$\frac{\xi - x}{\frac{df}{dx}} = \frac{\eta - y}{\frac{df}{dy}} = \frac{\zeta - z}{\frac{df}{dz}}.$$

In the series of tangent lines there are in general two (real or imaginary) lines, each of which meets the surface in a second consecutive point, or say it has three-point intersection with the surface; these are called the chief-tangents (Haupt-tangenten). The tangent-plane cuts the surface in a curve, having at the point of contact a node (double point), the tangents to the two branches being the chief-tangents.

In the case of a quadric surface the curve of intersection, *qua* curve of the second order, can only have a node by breaking up into a pair of lines; that is, every tangent-plane meets the surface in a pair of lines, or we have on the surface two singly infinite systems of lines; these are real for the hyperbolic paraboloid and the hyperboloid of one sheet, imaginary in other cases.

At each point of a surface the chief-tangents determine two directions; and passing along one of them to a consecutive point, and thence (without abrupt change of direction) along the new chief-tangent to a consecutive point, and so on, we have on the surface a chief-tangent curve; and there are, it is clear, two singly infinite series of such curves. In the case of a quadric surface, the curves are the right lines on the surface.

40. If at the point we draw in the tangent-plane two lines bisecting the angles between the chief-tangents, these lines (which are at right angles to each other) are called the principal tangents.¹ We have thus at each point of

¹ The point on the surface may be such that the directions of the principal tangents become arbitrary; the point is then an umbilicus. It is in the text assumed that the point on the surface is not an umbilicus.

the surface a set of rectangular axes, the normal and the two principal tangents

Proceeding from the point along a principal tangent to a consecutive point on the surface, and thence (without abrupt change of direction) along the new principal tangent to a consecutive point, and so on, we have on the surface a curve of curvature; there are, it is clear, two singly infinite series of such curves, cutting each other at right angles at each point of the surface.

Passing from the given point in an arbitrary direction to a consecutive point on the surface, the normal at the given point is not intersected by the normal at the consecutive point; but passing to the consecutive point along a curve of curvature (or, what is the same thing, along a principal tangent) the normal at the given point is intersected by the normal at the consecutive point, we have thus on the normal two centres of curvature, and the distances of these from the point on the surface are the two principal radii of curvature of the surface at that point; these are also the radii of curvature of the sections of the surface by planes through the normal and the two principal tangents respectively; or say they are the radii of curvature of the normal sections through the two principal tangents respectively. Take at the point the axis of z in the direction of the normal, and those of x and y in the directions of the principal tangents respectively, then, if the radii of curvature be a , b (the signs being such that the coordinates of the two centres of curvature are

$z = a$ and $z = b$ respectively), the surface has in the neighbourhood of the point the form of the paraboloid

$$z = \frac{x^2}{2a} + \frac{y^2}{2b},$$

and the chief-tangents are determined by the equation $0 = \frac{a^2}{2a} + \frac{y^2}{2b}$. The two centres of curvature may be on the same side of the point or on opposite sides, in the former case a and b have the same sign, the paraboloid is elliptic, and the chief-tangents are imaginary, in the latter case a and b have opposite signs, the paraboloid is hyperbolic, and the chief-tangents are real.

The normal sections of the surface and the paraboloid by the same plane have the same radius of curvature, and it thence readily follows that the radius of curvature of a normal section of the surface by a plane inclined at an angle θ to that of zx is given by the equation

$$\frac{1}{\rho} = \frac{\cos^2 \theta}{a} + \frac{\sin^2 \theta}{b}.$$

The section in question is that by a plane through the normal and a line in the tangent plane inclined at an angle θ to the principal tangent along the axis of x . To complete the theory, consider the section by a plane having the same trace upon the tangent plane, but inclined to the normal at an angle ϕ , then it is shown without difficulty (Meunier's theorem) that the radius of curvature of this inclined section of the surface is = $\rho \cos \phi$ (1 CA.)

GEORGE I., king of Great Britain and Ireland (*George Louis*, 1660-1727), born in 1660, was heir through his father Ernest Augustus to the hereditary lay bishopric of Osnabrück, and to the duchy of Calenberg, which formed one portion of the Hanoverian possessions of the house of Brunswick, whilst he secured the reversion of the other portion, the duchy of Celle or Zell, by his marriage (1682) with the heiress, his cousin Sophia Dorothea. The marriage was not a happy one. The morals of German courts in the end of the 17th century took their tone from the splendid profligacy of Versailles. It became the fashion for a prince to amuse himself with a mistress or more frequently with many mistresses simultaneously, and he was often content that the mistresses whom he favoured should be neither beautiful nor witty. George Louis followed the usual course. Count Königsmark—a handsome adventurer—seized the opportunity of paying court to the deserted wife. Conjugal infidelity was held at Hanover to be a privilege of the male sex. Count Königsmark was assassinated, Sophia Dorothea was divorced in 1694, and remained in seclusion till her death in 1726. When her descendant in the fourth generation attempted in England to call his wife to account for sins of which he was himself notoriously guilty, free-spoken public opinion reprobated the offence in no measured terms. In the Germany of the 17th century all free-spoken public opinion had been crushed out by the misery of the Thirty Years' War, and it was understood that princes were to arrange their domestic life according to their own pleasure.

The prince's father did much to raise the dignity of his family. By sending help to the emperor when he was struggling against the French and the Turks, he obtained the grant of a ninth electorate in 1692. His marriage with Sophia, the youngest daughter of Elizabeth the daughter of James I. of England, was not one which at first seemed likely to confer any prospect of advancement to his family. But though there were many persons whose birth gave them better claims than she had to the English crown,

she found herself, upon the death of the duke of Gloucester, the next Protestant heir after Anne. The Act of Settlement in 1701 secured the inheritance to herself and her descendants. Being old and unambitious she rather permitted herself to be burdened with the honour than thrust herself forward to meet it. Her son George took a deeper interest in the matter. In his youth he had fought with determined courage in the wars of William III. Succeeding to the electorate on his father's death in 1698, he had sent a welcome reinforcement of Hanoverians to fight under Marlborough at Blenheim. With prudent persistence he attached himself closely to the Whigs and to Marlborough, refusing Tory offers of an independent command, and receiving in return for his fidelity a guarantee by the Dutch of his succession to England in the Barrier treaty of 1709. In 1714 when Anne was growing old, and Bolingbroke and the more reckless Tories were enquiring with the son of James II., the Whigs invited George's eldest son, who was duke of Cambridge, to visit England in order to be on the spot in case of need. Neither the elector nor his mother approved of a step which was likely to alienate the queen, and which was specially distasteful to himself, as he was on very bad terms with his son. Yet they did not set themselves against the strong wish of the party to which they looked for support, and it is possible that troubles would have arisen from any attempt to carry out the plan, if the death, first of the electress (May 28) and then of the queen (August 1, 1714), had not laid open George's way to the succession without further effort of his own.

In some respects the position of the new king was not unlike that of William III., a quarter of a century before. Both sovereigns were foreigners, with little knowledge of English politics and little interest in English legislation. Both sovereigns arrived at a time when party spirit had been running high, and when the task before the ruler was to still the waves of contention. In spite of the difference between an intellectually great man and an intellectually

small one, in spite too of the difference between the king who began by choosing his ministers from both parties, and the king who persisted in choosing his ministers from only one, the work of pacification was accomplished by George even more thoroughly than by William.

George I was fortunate in arriving in England when a great military struggle had come to an end. He had therefore no reason to call upon the nation to make great sacrifices. All that he wanted was to secure for himself and his family a high position which he hardly knew how to occupy, to fill the pockets of his German attendants and his German mistresses, to get away as often as possible from the uncongenial islanders whose language he was unable to speak, and to use the strength of England to obtain petty advantages for his German principality. In order to do this he attached himself entirely to the Whig party, though he refused to place himself at the disposal of its leaders. He gave his confidence, not to Somers and Wharton and Marlborough, but to Stanhope and Townshend, the statesmen of the second rank. At first he seemed to be playing a dangerous game. The Tories, whom he rejected, were numerically superior to their adversaries, and were strong in the support of the country gentlemen and the country clergy. The strength of the Whigs lay in the towns and in the higher aristocracy. Below both parties lay the mass of the nation, which cared nothing for politics except in special seasons of excitement, and which asked only to be let alone. In 1715 a Jacobite insurrection in the north, supported by the appearance of the Pretender, the son of James II, in Scotland, was suppressed, and its suppression not only gave to the Government a character of stability, but displayed its adversaries in an unfavourable light as the disturbers of the peace.

Even this advantage, however, would have been thrown away, if the Whigs in power had continued to be animated by violent party spirit. What really happened was that the Tory leaders were excluded from office, but that the principles and prejudices of the Tories were admitted to their full weight in the policy of the Government. The natural result followed. The leaders to whom no regard was paid continued in opposition. The rank and file who would personally have gained nothing by a party victory were conciliated into quiescence.

This mingling of two policies was conspicuous both in the foreign and the domestic actions of the reign. In the days of Queen Anne, the Whig party had advocated the continuance of war with a view to the complete humiliation of the king of France, whom they feared as the protector of the Pretender, and in whose family connexion with the king of Spain they saw a danger for England. The Tory party on the other hand had been the authors of the peace of Utrecht, and held that France was sufficiently depressed. A fortunate concurrence of circumstances enabled George's ministers, by an alliance with the regent of France, the duke of Orleans, to pursue at the same time the Whig policy of separating France from Spain and from the cause of the Pretender, and the Tory policy of the maintenance of a good understanding with their neighbour across the Channel. The same eclecticism was discernible in the proceedings of the home Government. The Whigs were conciliated by the repeal of the Schism Act and the Occasional Conformity Act, whilst the Tories were conciliated by the maintenance of the Test Act in all its vigour. The satisfaction of the masses was increased by the general well-being of the nation.

Very little of all that was thus accomplished was directly owing to George I. The policy of the reign is the policy of his ministers. Stanhope and Townshend from 1714 to 1717 were mainly occupied with the defence of the Hanoverian settlement. After the dismissal of the latter in 1717,

Stanhope in conjunction with Sunderland took up a more decided Whig policy. The Occasional Conformity Act and the Schism Act were repealed in 1719. But the wish of the liberal Whigs to modify if not to repeal the Test Act remained unsatisfied. In the following year the bursting of the South Sea bubble, and the subsequent deaths of Stanhope in 1721 and of Sunderland in 1722, cleared the way for the accession to power of Sir Robert Walpole, to whom and not to the king was due the conciliatory policy which quieted Tory opposition by abstaining from pushing Whig principles to their legitimate consequences.

Nevertheless something of the honour due to Walpole must be reckoned to the king's credit. It is evident that at his accession his decisions were by no means unimportant. The royal authority was still able within certain limits to make its own terms. This support was so necessary to the Whigs that they made no resistance when he threw aside their leaders on his arrival in England. When by his personal intervention he dismissed Townshend and appointed Sunderland, he had no such social and parliamentary combination to fear as that which almost mastered his great-grandson in his struggle for power. If such a combination arose before the end of his reign it was owing more to his omitting to fulfil the duties of his station than from the necessity of the case. As he could talk no English, and his ministers could talk no German, he absented himself from the meetings of the cabinet, and his frequent absences from England and his want of interest in English politics strengthened the cabinet in its tendency to assert an independent position. Walpole at last by his skill in the management of parliament rose as a subject into the almost royal position denoted by the name of prime minister. In connexion with Walpole the force of wealth and station established the Whig aristocracy in a point of vantage from which it was afterwards difficult to dislodge them. Yet, though George had allowed the power which had been exercised by William and Anne to slip through his hands, it was understood to the last that if he chose to exert himself he might cease to be a mere cipher in the conduct of affairs. As late as in 1737 Bolingbroke gained over one of the king's mistresses, the duchess of Kendal; and though her support of the fallen Jacobite took no effect, Walpole was not without fear that her reiterated entreaties would lead to his dismissal. The king's death in a carriage on his way to Hanover, in the night between 10th and 11th June in the same year, put an end to these apprehensions.

His only children were his successor George II., and Sophia Dorothea (1687-1757), who married in 1706 Frederick William, crown prince (afterwards king) of Prussia. She was the mother of Frederick the Great. (S. R. G.)

GEORGE II. (*George Augustus*, 1683-1760), the only son of George I., was born in 1683. In 1705 he married Wilhelmina Caroline of Anspach. In 1706 he was created earl of Cambridge. In 1708 he fought bravely at Oudenarde. At his father's accession to the English throne he was thirty-one years of age. He was already on bad terms with his father. The position of an heir-apparent is in no case an easy one to fill with dignity, and the ill treatment of the prince's mother by his father was not likely to strengthen in him a reverence for paternal authority. It was most unwillingly that, on his first journey to Hanover in 1716, George I. appointed the prince of Wales guardian of the realm during his absence. In 1717 the existing ill feeling ripened into an open breach. At the baptism of one of his children, the prince selected one godfather whilst the king persisted in selecting another. The young man spoke angrily, was ordered into arrest, and was subsequently commanded to leave St James's, and to be excluded from all court ceremonies. The prince took

up his residence at Leicester House, and did everything in his power to support the opposition against his father's ministers.

When therefore George I. died in 1727, it was generally supposed that Walpole would be at once dismissed. The first direction of the new king was that Sir Spencer Compton would draw up the speech in which he was to announce to the Privy Council his accession. Compton, not knowing how to set about his task, applied to Walpole for aid. The queen took advantage of this evidence of incapacity, advocated Walpole's cause with her husband, and procured his continuance in office. This curious scene was indicative of the course likely to be taken by the new sovereign. His own mind was incapable of rising above the meanest details of business. He made war in the spirit of a drill-sergeant, and he economized his income with the minute regularity of a clerk. A blunder of a master of the ceremonies in marshalling the attendants on a levee put him out of temper. He took the greatest pleasure in counting his money piece by piece, and he never forgot a date. He was above all things methodical and regular. "He seems," said one who knew him well, "to think his living done a thing to-day an unanswerable reason for his doing it to-morrow."

Most men so utterly immersed in details would be very impracticable to deal with. They would obstinately refuse to listen to a wisdom and prudence which meant nothing in their ears, and which brought home to them a sense of their own inferiority. It was the happy peculiarity of George II. that he was exempt from this failing. He seemed to have an instinctive understanding that such and such persons were either wiser or even stronger than himself, and when he had once discovered that, he gave way with scarcely a struggle. Thus it was that, though in his domestic relations he was as loose a liver as his father had been, he allowed himself to be guided by the wise but unobtrusive counsels of his wife until her death in 1737, and that when once he had recognized Walpole's superiority he allowed himself to be guided by the political sagacity of the great minister. It is difficult to exaggerate the importance of such a temper upon the development of the constitution. The apathy of the nation in all but the most exciting political questions, fostered by the calculated conservatism of Walpole, had thrown power into the hands of the great landowners. They maintained their authority by supporting a minister who was ready to make use of corruption, wherever corruption was likely to be useful, and who could veil over the baseness of the means which he employed by his talents in debate and in finance. To shake off a combination so strong would not have been easy. George II. submitted to it without a struggle.

So strong indeed had the Whig aristocracy grown that it began to lose its cohesion. Walpole was determined to monopolize power, and he dismissed from office all who ventured to oppose him. An opposition formidable in talents was gradually formed. In its composite ranks were to be found Tories and discontented Whigs, discarded official hacks who were hungry for the emoluments of office, and youthful purists who fancied that if Walpole were removed, bribes and pensions would cease to be attractive to a corrupt generation. Behind them was Bolingbroke, excluded from parliament but suggesting every party move. In 1737 the opposition acquired the support of Frederick prince of Wales. The young man, weak and headstrong, rebelled against the strict discipline exacted by his father. His marriage in 1736 to Augusta of Saxony brought on an open quarrel. In 1737 just as the princess of Wales was about to give birth to her first child, she was hurried away by her husband from Hampton Court to St James's Palace at the imminent risk of her life, simply in order that the prince

might show his spite to his father who had provided all necessary attendance at the former place. George ordered his son to quit St James's, and to absent himself from court. Frederick in disgrace gave the support of his name, and he had nothing else to give, to the Opposition. Later in the year 1737, on November 20, Queen Caroline died. In 1742 Walpole, weighed down by the unpopularity both of his reluctance to engage in a war with Spain and of his supposed remissness in conducting the operations of that war, was driven from office. His successors formed a composite ministry in which Walpole's old colleagues and Walpole's old opponents were alike to be found.

The years which followed settled conclusively, at least for this reign, the constitutional question of the power of appointing ministers. The war between Spain and England had broken out in 1739. In 1741 the death of the emperor Charles VI. brought on the war of the Austrian succession. The position of George II. as a Hanoverian prince drew him to the side of Maria Theresa through jealousy of the rising Prussian monarchy. Jealousy of France led England in the same direction, and in 1741 a subsidy of £800,000 was voted to Maria Theresa. The king himself went to Germany and attempted to carry on the war according to his own notions. Those notions led him to regard the safety of Hanover as of far more importance than the wishes of England. Finding that a French army was about to march upon his German states, he concluded with France a treaty of neutrality for a year without consulting a single English minister. In England the news was received with feelings of disgust. The expenditure of English money and troops was to be thrown uselessly away as soon as it appeared that Hanover was in the slightest danger. In 1742 Walpole was no longer in office. Lord Wilmington, the nominal head of the ministry, was a mere cipher. The ablest and most energetic of his colleagues, Lord Carteret, attached himself specially to the king, and sought to maintain himself in power by his special favour and by brilliant achievements in diplomacy.

In part at least by Carteret's mediation the peace of Breslau was signed, by which Maria Theresa ceded Silesia to Frederick (July 28, 1742). Thus relieved on her northern frontier, she struck out vigorously towards the west. Bavaria was overrun by her troops. In the beginning of 1743 one French army was driven across the Rhine. On June 27th another French army was defeated by George II. in person at Dettingen. Victory brought elation to Maria Theresa. Her war of defence was turned into a war of vengeance. Bavaria was to be annexed. The French frontier was to be driven back. George II. and Carteret after some hesitation placed themselves on her side. Of the public opinion of the political classes in England they took no thought. Hanoverian troops were indeed to be employed in the war, but they were to be taken into British pay. Collisions between British and Hanoverian officers were frequent. A storm arose against the preference shown to Hanoverian interests. After a brief struggle Carteret, having become Lord Granville by his mother's death, was driven from office in November 1744.

Henry Pelham, who had become prime minister in the preceding year, thus saw himself established in power. By the acceptance of this ministry, the king acknowledged that the function of choosing a ministry and directing a policy had passed from his hands. In 1745 indeed he recalled Granville, but a few days were sufficient to convince him of the futility of his attempt, and the effort to exclude Pitt at a later time proved equally fruitless.

Important as were the events of the remainder of the reign, therefore, they can hardly be grouped round the name

of George II. The resistance to the invasion of the young Pretender in 1745, the peace of Aix-la-Chapelle in 1748, the great war ministry of Pitt at the close of the reign, did not receive their impulse from him. He had indeed done his best to exclude Pitt from office. He disliked him on account of his opposition in former years to the sacrifices demanded by the Hanoverian connexion. When in 1756 Pitt became secretary of state in the Devonshire administration, the King bore the yoke with difficulty. Early in the next year he complained of Pitt's long speeches as being above his comprehension, and on April 5, 1757, he dismissed him, only to take him back shortly after, when Pitt, coalescing with Newcastle, became master of the situation. Before Pitt's dismissal George II. had for once an opportunity of placing himself on the popular side, though, as was the case of his grandson during the American war, it was when the popular side happened to be in the wrong. In the true spirit of a martinet, he wished to see Admiral Byng executed. Pitt urged the wish of the House of Commons to have him pardoned. "Sir," replied the king, "you have taught me to look for the sense of my subjects in another place than in the House of Commons." When George II. died in 1760, he left behind him a settled understanding that the monarchy was one of the least of the forces by which the policy of the country was directed. To this end he had contributed much by his disregard of English opinion in 1743, but it may fairly be added that, but for his readiness to give way to irresistible adversaries, the struggle might have been far more bitter and severe than it was.

Of the connexion between Hanover and England in this reign two memorials remain more pleasant to contemplate than the records of parliamentary and ministerial intrigues. With the support of George II., amidst the derision of the English fashionable world, the Hanoverian Handel produced in England those masterpieces which have given delight to millions, whilst the foundation of the university of Göttingen by the same king opened a door through which English political ideas afterwards penetrated into Germany.

George II. had three sons,—Frederick Louis (1707-1751); George William (1717-1718), and William Augustus, duke of Cumberland (1721-1766); and five daughters, Anne (1709-1759), married to William, prince of Orange, 1734; Amelia Sophia Eleonora (1711-1786); Elizabeth Caroline (1713-1787); Mary (1723-1772), married to Frederick, landgrave of Hesse Cassel, 1740; Louisa (1724-1751), married to Frederick V., king of Denmark, 1743. (s. n. c.)

GEORGE III. (*George William Frederick*, 1738-1820), born 4th June 1738, was the son of Frederick prince of Wales and the grandson of George II., whom he succeeded in 1760. After his father's death in 1751 he had been educated in seclusion from the fashionable world under the care of his mother and of her favourite counsellor the earl of Bute. He had been taught to revere the maxims of Bolingbroke's "Patriot King," and to believe that it was his appointed task in life to break the power of the Whig houses resting upon extensive property and the influence of patronage and corruption.

That power had already been gravely shaken. The Whigs from their incompetency were obliged when the Seven Years' War broke out to leave its management in the hands of William Pitt. The nation learned to applaud the great war minister who succeeded where others had failed, and whose immaculate purity put to shame the ruck of barterers of votes for places and pensions. In some sort the work of the new king was the continuation of the work of Pitt. But his methods were very different. He did not appeal to any widely spread feeling or prejudice; nor did he disdain the use of the arts which had maintained his

opponents in power. The patronage of the crown was to be really as well as nominally his own, and he calculated, not without reason, that men would feel more flattered in accepting a place from a king than from a minister. The new Toryism of which he was the founder was no recurrence to the Toryism of the days of Charles II. or even of Anne. The question of the amount of toleration to be accorded to Dissenters had been entirely laid asleep. The point at issue was whether the crown should be replaced in the position which George I. might have occupied at the beginning of his reign, selecting the ministers and influencing the deliberations of the cabinet. For this struggle George III. possessed no inconsiderable advantages. With an inflexible tenacity of purpose, he was always ready to give way when resistance was really hopeless. As the first English-born sovereign of his house, speaking from his birth the language of his subjects, he found a way to the hearts of many who never regarded his predecessors as other than foreign intruders. The contrast, too, between the pure domestic life which he led with his wife Charlotte of Mecklenburg-Strelitz, whom he married in 1761, and the habits of three generations of his house, told in his favour with the vast majority of his subjects. Even his marriage had been a sacrifice to duty. Soon after his accession he had fallen in love with Lady Sarah Lennox, and had been observed to ride morning by morning along the Kensington Road, from which the object of his affections was to be seen from the lawn of Holland House making hay, or engaged in some other ostensible employment. Before the year was over Lady Sarah appeared as one of the queen's bridesmaids, and she was herself married to Sir Charles Bunbury in 1762.

At first everything seemed easy to him. Pitt had come to be regarded by his own colleagues as a minister who would pursue war at any price, and in getting rid of Pitt in 1761 and in carrying on the negotiations which led to the peace of Paris in 1763, the king was able to gather round him many persons who would not be willing to acquiesce in any permanent change in the system of government. With the signature of the peace his real difficulties began. The Whig houses, indeed, were divided amongst themselves by personal rivalries. But they were none of them inclined to let power and the advantages of power slip from their hands without a struggle. For some years a contest of influence was carried on without dignity and without any worthy aim. The king was not strong enough to impose upon parliament a ministry of his own choice. But he gathered round himself a body of dependants known as the king's friends, who were secure of his favour, and who voted one way or the other according to his wishes. Under these circumstances no ministry could possibly be stable, and yet every ministry was strong enough to impose some conditions on the king. Lord Bute, the king's first choice, resigned from a sense of his own incompetency in 1763. George Grenville was in office till 1769; the marquis of Rockingham till 1766; Pitt, becoming earl of Chatham, till illness compelled him to retire from the conduct of affairs in 1767, when he was succeeded by the duke of Grafton. But a struggle of interests could gain no real strength for any Government, and the only chance the king had of effecting a permanent change in the balance of power lay in the possibility of his associating himself with some phase of strong national feeling, as Pitt had associated himself with the war feeling caused by the dissatisfaction spread by the weakness and ineptitude of his predecessors.

Such a chance was offered by the question of the right to tax America. The notion that England was justified in throwing on America part of the expenses caused in the late war was popular in the country, and no one adopted it more pertinaciously than George III. At the bottom the

position which he assumed was as contrary to the principles of parliamentary government as the encroachments of Charles I. had been. But it was veiled in the eyes of Englishmen by the prominence given to the power of the British parliament rather than to the power of the British king. In fact the theory of parliamentary government, like most theories after their truth has long been universally acknowledged, had become a superstition. Parliaments were held to be properly vested with authority, not because they adequately represented the national will, but simply because they were parliaments. There were thousands of people in England to whom it never occurred that there was any good reason why a British parliament should be allowed to levy a duty on tea in the London docks and should not be allowed to levy a duty on tea at the wharves of Boston. Undoubtedly George III. derived great strength from his honest participation in this mistake. Contending upon parliamentary forms, he did not wound the susceptibilities of members of parliament, and when at last in 1770 he appointed Lord North—a minister of his own selection—prime minister, the object of his ambition was achieved with the concurrence of a large body of politicians who had nothing in common with the servile band of the king's friends.

As long as the struggle with America was carried on with any hope of success they gained that kind of support which is always forthcoming to a Government which shares in the errors and prejudices of its subjects. The expulsion of Wilkes from the House of Commons in 1769, and the refusal of the House to accept him as a member after his re-election, raised a grave constitutional question in which the king was wholly in the wrong; and Wilkes was popular in London and Middlesex. But his case roused no national indignation, and when in 1774 those sharp measures were taken with Boston which led to the commencement of the American rebellion in 1775, the opposition to the course taken by the king made little way either in parliament or in the country. Burke might point out the folly and inexpediency of the proceedings of the Government. Chatham might point out that the true spirit of English government was to be representative, and that that spirit was being violated at home and abroad. George III., who thought that the first duty of the Americans was to obey himself, had on his side the mass of unreflecting Englishmen who thought that the first duty of all colonists was to be useful and submissive to the mother-country. The natural dislike of every country engaged in war to see itself defeated was on his side, and when the news of Burgoyne's surrender at Saratoga arrived in 1777, subscriptions of money to raise new regiments poured freely in.

In March 1778 the French ambassador in London announced that a treaty of friendship and commerce had been concluded between France and the new United States of America. Lord North was anxious to resign power into stronger hands, and begged the king to receive Chatham as his prime minister. The king would not hear of it. He would have nothing to say to "that perfidious man" unless he would humble himself to enter the ministry as North's subordinate. Chatham naturally refused to do anything of the kind, and his death in the course of the year relieved the king of the danger of being again overruled by too overbearing a minister. England was now at war with France, and in 1779 she was also at war with Spain.

George III. was still able to control the disposition of office. He could not control the course of events. His very ministers gave up the struggle as hopeless long before he would acknowledge the true state of the case. Before the end of 1779, two of the leading members of the cabinet, Lords Gower and Weymouth, resigned rather than bear the responsibility of so ruinous an enterprise as the attempt to

overpower America and France together. Lord North retained office, but he acknowledged to the king that his own opinion was precisely the same as that of his late colleagues.

The year 1780 saw an agitation rising in the country for economical reform, an agitation very closely though indirectly connected with the war policy of the king. The public meetings held in the country on this subject have no unimportant place in the development of the constitution. Since the presentation of the Kentish Petition in the reign of William III. there had been from time to time upheavings of popular feeling against the doings of the legislature, which kept up the tradition that parliament existed in order to represent the nation. But these upheavings had all been so associated with ignorance and violence as to make it very difficult for men of sense to look with displeasure upon the existing emancipation of the House of Commons from popular control. The Sacheverell riots, the violent attacks upon the Excise Bill, the no less violent advocacy of the Spanish war, the declamations of the supporters of Wilkes at a more recent time, and even in this very year the Gordon riots, were not likely to make thoughtful men anxious to place real power in the hands of the classes from whom such exhibitions of folly proceeded. But the movement for economical reform was of a very different kind. It was carried on soberly in manner, and with a definite practical object. It asked for no more than the king ought to have been willing to concede. It attacked useless expenditure upon sinecures and unnecessary offices in the household, the only use of which was to spread abroad corruption amongst the upper classes. George III. could not bear to be interfered with at all, or to surrender any element of power which had served him in his long struggle with the Whigs. He held out for more than another year. The news of the capitulation of York Town reached London on November 26, 1781. On March 20, 1782, Lord North resigned.

George III. accepted the consequences of defeat. He called the marquis of Rockingham to office at the head of a ministry composed of pure Whigs and of the disciples of the late earl of Chatham, and he authorized the new ministry to open negotiations for peace. Their hands were greatly strengthened by Rodney's victory over the French fleet, and the failure of the combined French and Spanish attack upon Gibraltar; and before the end of 1782 a provisional treaty was signed with America, preliminaries of peace with France and Spain being signed early in the following year. On September 3, 1783, the definitive treaties with the three countries were simultaneously concluded. "Sir," said the king to Mr. Adams the first minister of the United States of America accredited to him, "I wish you to believe, and that it may be understood in America, that I have done nothing in the late contest but what I thought myself indisposably bound to do by the duty which I owed to my people. I will be very frank with you. I was the last to consent to the separation; but the separation having been made and having become inevitable, I have always said, as I say now, that I would be the first to meet the friendship of the United States as an independent power."

Long before the signature of the treaties Rockingham died (July 1, 1782). The king chose Lord Shelburne, the head of the Chatham section of the Government, to be prime minister. Fox and the followers of Rockingham refused to serve except under the duke of Portland, a minister of their own selection, and resigned office. The old constitutional struggle of the reign was now to be fought out once more. Fox, too weak to obtain a majority alone, coalesced with Lord North, and defeated Shelburne in the House of Commons on February 17, 1783. On April 2 the coalition took office, with Portland as nominal

prime minister, and Fox and North the secretaries of state as its real heads.

This attempt to impose upon him a ministry which he disliked made the king very angry. But the new cabinet had a large majority in the House of Commons, and the only chance of resisting it lay in an appeal to the country against the House of Commons. Such an appeal was not likely to be responded to unless the ministers discredited themselves with the nation. George III. therefore waited his time. Though a coalition between men bitterly opposed to one another in all political principles and drawn together by nothing but love of office was in itself discreditable, it needed some more positive cause of dissatisfaction to arouse the constituencies, which were by no means so ready to interfere in political disputes at that time as they are now. Such dissatisfaction was given by the India Bill, drawn up by Burke. As soon as it had passed through the Commons the king hastened to procure its rejection in the House of Lords by his personal intervention with the Peers. He authorized Lord Temple to declare in his name that he would count any peer who voted for the Bill as his enemy. On December 17, 1783, the Bill was thrown out. The next day ministers were dismissed. William Pitt became prime minister. After some weeks' struggle with a constantly decreasing majority in the Commons, the king dissolved parliament on March 25, 1784. The country rallied round the crown and the young minister, and Pitt was firmly established in office.

Since the publication of a letter from Mr Orde in Lord E. Fitzmaurice's *Life of Shelburne* (iii. 393) there can be no reasonable doubt that Pitt not only took advantage of the king's intervention in the Lords, but was cognizant of the intrigue before it was actually carried out. It was upon him, too, that the weight of reconciling the country to an administration formed under such circumstances lay. How he acquitted himself under the task, what were his great achievements, and what his still greater unaccomplished projects should be told in connexion with his name rather than with that of the king. The general result, so far as George III. was concerned, was that to all outward appearance he had won the great battle of his life. It was he who was to appoint the prime minister, not any clique resting on a parliamentary support. But the circumstances under which the victory was won were such as to place the constitution in a position very different from that in which it would have been if the victory had been gained earlier in the reign. Intrigue there was indeed in 1783 and 1784 as there had been twenty years before. Parliamentary support was conciliated by Pitt by the grant of royal favours as it had been in the days of Bute. The actual blow was struck by a most questionable message to individual peers. But the main result of the whole political situation was that George III. had gone a long way towards disentangling the reality of parliamentary government from its accidents. His ministry finally stood because it had appealed to the constituencies against their representatives. At the present day it has properly become a constitutional axiom that no such appeal should be made by the crown itself. But it may reasonably be doubted whether any one but the king was at that time capable of making the appeal. Lord Shelburne, the leader of the ministry expelled by the coalition, was unpopular in the country, and the younger Pitt had not had time to make his great abilities known beyond a limited circle. The real question for the constitutional historian to settle is not whether under ordinary circumstances a king is the proper person to place himself really as well as nominally at the head of the government; but whether under the special circumstances which existed in 1783 it was not better that the king should call upon the people to support him, than that government should be left

in the hands of men who rested their power on close boroughs and the dispensation of patronage, without looking beyond the walls of the House of Commons for support.

Of the glories of Pitt's ministry this is not the place to write. That the king gained credit by them far beyond his own deserts is beyond a doubt. Nor can there be any reasonable doubt that his own example of domestic propriety did much to strengthen the position of his minister. It is true that that life was unsufferably dull. No gleams of literary or artistic taste lightened it up. The dependants of the court became inured to dull routine unchequered by loving sympathy. The sons of the household were driven by the sheer weariness of such an existence into the coarsest prodigality. But all this was not visible from a distance. The tide of moral and religious improvement which had set in in England since the days of Wesley brought popularity to a king who was faithful to his wife, in the same way that the tide of manufacturing industry and scientific progress brought popularity to the minister who in some measure translated into practice the principles of the *Wealth of Nations*.

Nor were there wanting subjects of importance beyond the circle of politics in which George III. showed a lively interest. The voyages of discovery which made known so large a part of the islands and coasts of the Pacific Ocean received from him a warm support. In the early days of the Royal Academy, its finances were strengthened by liberal grants from the privy purse. His favourite pursuit, however, was farming. When Arthur Young was issuing his *Annals of Agriculture*, he was supplied with information by the king, under the assumed name of Mr Ralph Robinson, relating to a farm at Petersham.

The life of the king was suddenly clouded over. Early in his reign, in 1765, he had been out of health, and it is now known—that was studiously concealed at the time—that symptoms of mental aberration were even then to be perceived. In October 1788 he was again out of health, and in the beginning of the following month his insanity was beyond a doubt. Whilst Pitt and Fox were contending in the House of Commons over the terms on which the regency should be committed to the prince of Wales, the king was a helpless victim to the ignorance of physicians and the brutalities of his servants. At last Dr Willis, who had made himself a name by prescribing gentleness instead of rigour in the treatment of the insane, was called in. Under his more humane management the king rapidly recovered. Before the end of February 1789 he was able to write to Pitt thanking him for his warm support of his interests during his illness. On April 23 he went in person to St Paul's to return thanks for his recovery.

The popular enthusiasm which burst forth around St Paul's was but a foretaste of a popularity far more universal. The French Revolution frightened the great Whig landowners till they made their peace with the king. Those who thought that the true basis of government was aristocratical were now of one mind with those who thought that the true basis of government was monarchical; and these two classes were joined by a far larger multitude which had no political ideas whatever, but which had a moral horror of the guillotine. As Elizabeth had once been the symbol of resistance to Spain, George was now the symbol of resistance to France. He was not, however, more than the symbol. He allowed Pitt to levy taxes and incur debt, to launch armies to defeat, and to prosecute the English imitators of French revolutionary courses. At last, however, after the Union with Ireland was accomplished, he learned that Pitt was planning a scheme to relieve the Catholics from the disabilities under which they laboured. The plan was revealed to him by the chancellor, Lord Loughborough, a selfish and intriguing politician who had served all parties

in turn, and who sought to forward his own interests by falling in with the king's prejudices. George III. at once took up the position from which he never swerved. He declared that to grant concessions to the Catholics involved a breach of his coronation oath. All thinking men of a later generation are of opinion that the objection was untenable. But no one has ever doubted that the king was absolutely convinced of the serious nature of the objection, or that he believed the measure itself to be beyond measure injurious to church and state. Nor can there be any doubt that he had the English people behind him. Both in his peace ministry and in his war ministry Pitt had taken his stand on royal favour and on popular support. Both failed him alike now, and he resigned office at once. The shock to the king's mind was so great that it brought on a fresh attack of insanity. This time, however, the recovery was rapid. On March 14, 1801, Pitt's resignation was formally accepted, and the late speaker, Mr Addington, was installed in office as prime minister.

The king was well pleased with the change. He was never capable of appreciating high merit in any one; and he was unable to perceive that the question on which Pitt had resigned was more than an improper question, with which he ought never to have meddled. "Tell him," he said, in directing his physician to inform Pitt of his restoration to health, "I am now quite well, quite recovered from my illness, but what has he not to answer for, who has been the cause of my having been ill at all?" Addington was a minister after his own mind. Thoroughly honest and respectable, with about the same share of abilities as was possessed by the king himself, he was certainly not likely to startle the world by any flights of genius. But for one circumstance Addington's ministry would have lasted long. So strong was the reaction against the Revolution that the bulk of the nation was almost as suspicious of genius as the king himself. Not only was there no outcry for legislative reforms, but the very idea of reform was unpopular. The country gentlemen were predominant in parliament, and the country gentlemen as a body looked upon Addington with respect and affection. Such a minister was therefore admirably suited to preside over affairs at home in the existing state of opinion. But those who were content with inaction at home would not be content with inaction abroad. In time of peace Addington would have been popular for a season. In time of war even his warmest admirers could not say that he was the man to direct armies in the most terrible struggle which had ever been conducted by an English Government.

For the moment this difficulty was not felt. On October 1, 1801, preliminaries of peace were signed between England and France, to be converted into the definitive peace of Amiens on March 27, 1802. The ruler of France was now Napoleon Bonaparte, and few persons in England believed that he had any real purpose of bringing his aggressive violence to an end. "Do you know what I call this peace?" said the king; "an experimental peace, for it is nothing else. But it was unavoidable."

The king was right. On May 18, 1803, the declaration of war was laid before parliament. The war was accepted by all classes as inevitable, and the French preparations for an invasion of England roused the whole nation to a glow of enthusiasm only equalled by that felt when the Armada threatened our shores. On October 26 the king reviewed the London volunteers in Hyde Park. He found himself the centre of a great national movement with which he heartily sympathized, and which heartily sympathized with him.

On February 12, 1804, the king's mind was again affected. When he recovered, he found himself in the midst of a ministerial crisis. Public feeling allowed but

one opinion to prevail in the country,—that Pitt, not Addington, was the proper man to conduct the administration in time of war. Pitt was anxious to form an administration on a broad basis, including Fox and all prominent leaders of both parties. The king would not hear of the admission of Fox. His dislike of him was personal as well as political, as he knew that Fox had had a great share in drawing the prince of Wales into a life of profligacy. Pitt accepted the king's terms, and formed an administration in which he was the only man of real ability. Eminent men such as Lord Grenville refused to join a ministry from which the king had excluded a great statesman on purely personal grounds.

The whole question was reopened on Pitt's death on January 23, 1806. This time the king gave way. The ministry of All the Talents, as it was called, included Fox amongst its members. At first the king was observed to appear depressed at the necessity of surrender. But Fox's charm of manner soon gained upon him. "Mr Fox," said the king, "I little thought that you and I should ever meet again in this place, but I have no desire to look back upon old grievances, and you may rest assured I never shall remind you of them." On September 13 Fox died, and it was not long before the king and the ministry were openly in collision. The ministry proposed a measure enabling all subjects of the crown to serve in the army and navy in spite of religious disqualifications. The king objected even to so slight a modification of the laws against the Catholics and Dissenters, and the ministers consented to drop the bill. The king asked more than this. He demanded a written and positive engagement that this ministry would never, under any circumstances, propose to him "any measure of concession to the Catholics, or even connected with the question." The ministers very properly refused to bind themselves for the future. They were consequently turned out of office, and a new ministry was formed with the duke of Portland as first lord of the treasury and Mr Perceval as its real leader. The spirit of the new ministry was distinct hostility to the Catholic claims. On April 27, 1807, a dissolution of parliament was announced, and a majority in favour of the king's ministry was returned in the elections which speedily followed.

The elections of 1807, like the elections of 1784, gave the king the mastery of the situation. In other respects they were the counterpart of one another. In 1784 the country declared, though perhaps without any clear conception of what it was doing, for a wise and progressive policy. In 1807 it declared for an unwise and retrogressive policy, with a very clear understanding of what it meant. It is in his reliance upon the prejudices and ignorance of the country that the constitutional significance of the reign of George III. appears. Every strong Government derives its power from its representative character. At a time when the House of Commons was less really representative than at any other, a king was on the throne who represented the country in its good and bad qualities alike, in its hatred of revolutionary violence, its moral sturdiness, its contempt of foreigners, and its defiance of all ideas which were in any way strange. Therefore it was that his success was not permanently injurious to the working of the constitution as the success of Charles I. would have been. If he were followed by a king less English than himself, the strength of representative power would pass into other hands than those which held the sceptre.

The overthrow of the ministry of All the Talents was the last political act of constitutional importance in which George III. took part. The substitution of Perceval for Portland as the nominal head of the ministry in 1809 was not an event of any real significance, and in 1811 the reign practically came to an end. The king's reason finally broke

down after the death of the Princess Amelia, his favourite child. The remaining nine years of his life were passed in insanity and blindness, and when he died on January 29, 1820, in his eighty-second year, no political results were to be anticipated.

George III had nine sons. After his successor came Frederick, duke of York and Albany (1763-1837), William Henry, duke of Clarence, afterwards King William IV. (1765-1837), Edward Augustus, duke of Kent (1767-1825), father of Queen Victoria, Ernest Augustus, duke of Cumberland, afterwards king of Hanover (1771-1851), Augustus Frederick, duke of Sussex (1773-1843), Adolphus Frederick, duke of Cambridge (1774-1860), Octavius (1779-1783), Alfred (1780-1782). He had also six daughters—Charlotte Augusta (1766-1816), married in 1797 to Frederick, king of Wurtemberg, Augusta Sophia (1768-1840); Elizabeth (1770-1840), married Frederick, landgrave of Hesse-Homburg, 1818, Mary (1776-1857), married to William Frederick, duke of Gloucester, 1816; Sophia (1777-1848); Amelia (1783-1810). (s. n. c.)

GEORGE IV. (*George Augustus Frederick*, 1762-1830), lived long enough to strip the crown of the leadership of the nation which his father had won for it. Born on August 12, 1762, he was noted in the years of his early manhood for good looks, for ease of carriage, and graciousness of manner. He soon plunged into the whirl of sensual excitement. His life was passed in the grossest profligacy. He was false as well as hontious. His word was never to be trusted. Not even an occasional gleam of brightness lights up the dark picture of his career. If he now and then flung to a dependant a kindly word which cost him nothing, no serious project of well-doing ever occupied his thoughts. Politics had no attraction for him except so far as changes of Government might minister to his ease, or bring him money to be squandered in some new scheme of folly.

Such a character was probably beyond the reach of any education. But it is certain that the education which he received in the strict and formal domestic circle of his parents was only fitted to repel him from the path of virtue. His father became to him the type of uninteresting formality. He gladly sought the society of his father's Whig opponents, and was initiated by Fox and Sheridan in the vices of the fashionable world. In 1783 he naturally supported the coalition ministry which his father detested, and the coalition ministry in return proposed to raise his income from £50,000 to £100,000. The king saved the ministry from committing one more blunder in its career by refusing to sanction the proposition. In 1786 the prince's friends urged Pitt to increase the allowance, but Pitt refused to do anything of the kind. All the world knew that the money would be frittered away at the gambling table or in some other equally disreputable way. Applying to the king and getting a distinct refusal, the prince sold his horses and carriages, shut up his house, and dismissed his servants. As it was well known that these were not the expenses which had brought him to distress, he was only laughed at for his pains. A lower depth was soon reached. The prince fell in love with Mrs Fitzherbert who had been twice a widow at twenty-five. She was ready to marry him, but she would yield to him on no other terms. She was a Roman Catholic, and a marriage by the heir of the crown with a Roman Catholic forfeited his succession by the Act of Settlement. Nor, by the Royal Marriage Act, could he legally contract marriage even with a Protestant without his father's consent, unless at the end of a year after formal notice had been given, and then only if parliament had not expressed its disapprobation. Believing truly that he could contract no legal marriage with Mrs Fitzherbert, he was

quite ready to go through the form of marriage. Mrs Fitzherbert, holding that the performance of the ceremony by a priest of her church was of sacramental efficacy, was indifferent to the legality of the proceeding. The marriage took place. Not long afterwards, in April 1787, Alderman Newenham moved in the House of Commons for a grant in relief of the prince. In the course of debate allusion was made to a marriage which might bring in question the succession. Fox went to the prince, and was assured by him that the marriage had never even formally taken place. Fox, deceived by his apparent openness, came down to the House and assured the Commons that the whole story was a malicious falsehood. The next day a friend of Fox's opened his eyes to the trick which had been played on him. "I see by the papers, Mr Fox," he said, "that you have denied the fact of the marriage of the prince of Wales with Mrs Fitzherbert. You have been misinformed. I was present at that marriage." The prince was not content with his original falsehood. He threw out hints to his friends that Fox had exceeded his instructions. He led Mrs Fitzherbert to believe that Fox had uttered the denial suggested. "Only conceive, Ma'am," he said to her, "what Fox did yesterday. He went down to the House and denied that you and I were man and wife." The denial however cleared away for the moment one cause of the prince's unpopularity. With the consent of the Government he received an addition of £10,000 to his income, £161,000 to pay his debts, and £20,000 for the repairs of Carlton House. The temporary insanity of the king in 1788 again brought the prince's name prominently before the public. Fox maintained and Pitt denied that the prince of Wales, as the heir-apparent, had a right to assume the regency independently of any parliamentary vote. Pitt, with the support of both Houses, proposed to confer upon him the regency with certain restrictions. The recovery of the king in February 1789 put an end to the prince's hopes. During the king's illness he had been in the habit of amusing his companions by mimicry of his unfortunate father. The disgust caused by his behaviour had doubtless some part in the enthusiasm with which the king was received when he went in state to St Paul's to return thanks for his recovery. In 1795 the prince married Caroline of Brunswick, because his father would not pay his debts on any other terms. Her behaviour was light and flippant, and he was brutal and unloving. The ill-assorted pair soon parted, and soon after the birth of their only child, the Princess Charlotte, they were formally separated. With great unwillingness the House of Commons voted fresh sums of money to pay the prince's debts. In 1811 the prince at last became regent in consequence of his father's definite insanity. No one doubted at that time that it was in his power to change the ministry at his pleasure. He had always lived in close connexion with the Whig opposition, and he now empowered Lord Grenville to form a ministry. There soon arose differences of opinion between them on the answer to be returned to the address of the Houses, and the prince regent then informed the prime minister, Mr Perceval, that he should continue the existing ministry in office. The ground alleged by him for this desertion of his friends was the fear lest his father's recovery might be rendered impossible if he should come to hear of the advent of the Opposition to power. Lord Wellesley's resignation in February 1812 made the reconstruction of the ministry inevitable. As there was no longer any hope of the king's recovery, the former objection to a Whig administration no longer existed. Instead of taking the course of inviting the Whigs to take office, he asked them to join the existing administration. The Whig leaders however refused to join, on the ground that the question of the Catholic disabilities was too important to be shelved,

and that their difference of opinion with Mr Perceval was too glaring to be ignored. The prince regent was excessively angry, and continued Perceval in office till that minister's assassination on May 11, when he was succeeded by Lord Liverpool, after a negotiation in which the proposition of entering the cabinet was again made to the Whigs and rejected by them. In the military glories of the following years the prince regent had no share. When the allied sovereigns visited England in 1814, he played the part of host to perfection. So great was his unpopularity at home that hisses were heard in the streets as he accompanied his guests into the city. The disgust which his profligate and luxurious life caused amongst a people suffering from almost universal distress after the conclusion of the war rapidly increased. In 1817 the windows of the prince regent's carriage were broken as he was on his way to open parliament.

The death of George III. on January 29, 1820, gave to his son the title of king without in any way altering the position which he had now held for nine years. Indirectly, however, this change brought out a manifestation of popular feeling such as his father had never been subjected to even in the early days of his reign, when mobs were burning jack-boots and petticoats. The relations between the new king and his wife unavoidably became the subject of public discussion. In 1806 a charge against the princess of having given birth to an illegitimate child had been conclusively disproved, and the old king had consequently refused to withdraw her daughter, the Princess Charlotte, from her custody. When in the regency the prince was able to interfere, and prohibited his wife from seeing her daughter more than once a fortnight. On this, in 1813, the princess addressed to her husband a letter setting forth her complaints, and receiving no answer published it in the *Morning Chronicle*. The prince regent then referred the letter, together with all papers relating to the inquiry of 1806, to a body of twenty-three privy councillors for an opinion whether it was fit that the restrictions on the intercourse between the Princess Charlotte and her mothers should continue in force. All except two answered as the regent wished them to answer. But if the official leaning was towards the husband, the leaning of the general public was towards the wife of a man whose own life had not been such as to justify him in complaining of her whom he had thrust from him without a charge of any kind. Addresses of sympathy were sent up to the princess from the city of London and other public bodies. The discord again broke out in 1814 in consequence of the exclusion of the princess from court during the visit of the allied sovereigns. In August in that year she left England, and after a little time took up her abode in Italy. The accession of George IV. brought matters to a crisis. He ordered that no prayer for his wife as queen should be admitted into the Prayer Book. She at once challenged the accusation which was implied in this omission by returning to England. On June 7 she arrived in London. Before she left the Continent she had been informed that proceedings would be taken against her for adultery if she landed in England. Two years before, in 1818, commissioners had been sent to Milan to investigate charges against her, and their report, laid before the cabinet in 1819, was made the basis of the prosecution. On the day on which she arrived in London a message was laid before both Houses recommending the emanating evidence to parliament. A secret committee in the House of Lords after considering this evidence brought in a report on which the prime minister founded a Bill of Pains and Penalties to divorce the queen and to deprive her of her royal title. The Bill passed the three readings with diminished majorities, and when on the third reading it obtained only a majority of nine, it was aban-

doned by the Government. The king's unpopularity, great as it had been before, was now greater than ever. Public opinion, without troubling itself to ask whether the queen was guilty or not, was roused to indignation by the spectacle of such a charge being brought by a husband who had thrust away his wife to fight the battle of life alone, without protection or support, and who, whilst surrounding her with spies to detect, perhaps to invent, her acts of infidelity, was himself living in notorious adultery. In the following year (1821) she attempted to force her way into Westminster Abbey to take her place at the coronation. On this occasion the popular support failed her, and her death not long afterwards relieved the king from further annoyance.

Immediately after the death of the queen, the king set out for Ireland. He remained there but a short time, and his effusive declaration that rank, station, honours, were nothing compared with the exalted happiness of living in the hearts of his Irish subjects gained him a momentary popularity which was beyond his attainment in a country where he was better known. His reception in Dublin encouraged him to attempt a visit to Edinburgh in the following year (August 1822). Since Charles II. had come to play the sorry part of a covenanted king in 1650 no sovereign of the country had set foot on Scottish soil. Sir Walter Scott took the leading part in organizing his reception. The enthusiasm with which he was received equalled, if it did not surpass, the enthusiasm with which he had been received in Dublin. But the qualities which enabled him to fix the fleeting sympathies of the moment were not such as would enable him to exercise the influence in the government which had been indubitably possessed by his father. He returned from Edinburgh to face the question of the appointment of a secretary of state which had been raised by the death of Lord Londonderry, better known to the world by his earlier title of Castlereagh. It was upon the question of the appointment of ministers that the battle between the Whigs and the king had been fought in the reign of George III. George IV. had neither the firmness nor the moral weight to hold the reins which his father had grasped. He disliked Canning for having taken his wife's side very much as his father had disliked Fox for taking his own. But Lord Liverpool insisted on Canning's admission to office, and the king gave way. Tacitly and without a struggle the constitutional victory of the last reign was surrendered. But it was not surrendered to the same foe as that from which it had been won. The coalition ministry in 1784 rested on the great landowners and the proprietors of rotten boroughs. Lord Liverpool's ministry had hitherto not been very enlightened, and it supported itself to a great extent upon a narrow constituency. But it did appeal to public opinion in a way that the coalition did not, and what it wanted itself in popular support would be supplied by its successors. What one king had gained from a clique another gave up to the nation. Once more, on Lord Liverpool's death in 1827, the same question was tried with the same result. The king not only disliked Canning personally, but he was opposed to Canning's policy. Yet after some hesitation he accepted Canning as prime minister; and when, after Canning's death and the short ministry of Lord Godolphin, the king in 1828 authorized the duke of Wellington to form a ministry, he was content to lay down the principle that the members of it were not expected to be unanimous on the Catholic question. When in 1829 the Wellington ministry unexpectedly proposed to introduce a Bill to remove the disabilities of the Catholics, he feebly strove against the proposal and quickly withdrew his opposition. The worn-out debauchee had neither the merit of acquiescing in the change nor the courage to resist it.

George IV. died on June 26, 1830. He had rendered to

the constitution of his country the service of tacitly abandoning a position which had been perhaps necessarily achieved by his father, but which it was not desirable that the sovereigns of England should permanently occupy.

His only child by his wife Queen Caroline was the Princess Charlotte Augusta, married in 1816 to Leopold of Saxe-Coburg, afterwards king of the Belgians. She died in childbirth November 6, 1817. (s. R. C.)

GEORGE or CAPPADOCIA, who from 356 to 361 was Arrian archbishop of Alexandria, was born about the beginning of the 4th century. According to Ammannus (xxii. 11), he was a native of Epiphania, in Cilicia; but universal tradition makes him a Cappadocian. Gregory Nazianzen tells us that his father was a fuller, and that he himself soon became notorious as a parasite of so mean a type that he would "sell himself for a cake." By his powers of insinuation he succeeded in obtaining a lucrative contract for supplying bacon to the army, but fulfilled its terms so ill that he was soon compelled to abscond after he had with difficulty escaped death at the hands of the indignant soldiers. After many wanderings, in the course of which he seems to have lived for some time at Constantinople, and to have amassed a considerable fortune as receiver of taxes, he ultimately reached Alexandria. It is not known how or when he obtained ecclesiastical orders; but, after Athanasius had been banished in 356, George was promoted by the influence of the then prevalent Arrian faction to the vacant see. His persecutions and oppressions of the orthodox ultimately raised a rebellion which compelled him to flee for his life; but his authority was restored, although with difficulty, by a military demonstration. Untaught by experience he resumed his course of selfish tyranny over Christians and heathen alike, and raised the irritation of the populace to such a pitch that, within a few days after the accession of Julian, they rose *en masse*, dragged him out of prison, where he had been placed by the magistrates for safety, paraded him with every indignity through the streets on the back of a camel, burnt his dead body, and cast the ashes into the sea (December 24, 361). With much that was sordid and brutal in his character George combined a highly cultivated literary taste, and in the course of his chequered career he had found the means of collecting a splendid library, which Julian ordered to be carefully preserved and conveyed to Antioch for his own use. The original sources for the facts of the life of George of Cappadocia are Ammannus, Gregory Nazianzen, Epiphanius, and Athanasius. In modern times his character has been drawn with graphic fidelity by Gibbon in the 23d chapter of the *Decline and Fall*.

GEORGE, SAINT, according to Metaphrastes the Byzantine hagiologist, whose narrative is substantially repeated in the Roman *Acta Sanctorum* and in the Spanish breviary, was born in Cappadocia of noble Christian parents, from whom he received a careful religious training. Having embraced the profession of a soldier, he rapidly rose under Diocletian to high military rank. When that emperor had begun to manifest a pronounced hostility towards Christianity George sought a personal interview with him, in which he made deliberate profession of his faith, and, earnestly remonstrating against the persecution which had begun, resigned his commission. He was immediately laid under arrest, and after various tortures, finally put to death at Nicomedia (or, according to other accounts, at Lydda) April 23, 303. His festival is observed on that anniversary by the entire Roman Church as a semi-duplex, and by the Spanish Catholics as a duplex of the first class with an octave. The day is also celebrated as a principal feast in the Greek Church, where the saint is distinguished by the titles *μεγαλόμαρτυρ* and *τροπαιοφόρος*.

In the canon of Pope Gelasius (494) George is mentioned

among the martyrs whom the Roman Church venerates, but whose gesta it does not read.¹ The language implies that even at that date much had been written concerning him, but little that the Catholic Church could accept as trustworthy. Numerous traits from the biography of the heretical archbishop had already crept, it would seem, into the acts of the orthodox soldier, and it was feared that any vigorous attempt to eliminate these would leave but a small residue of fact. Modern investigation has proved that apprehension to have been well-founded, for even on the Catholic side in the controversy regarding the existence and character of St George, the chief contention is simply the improbability that within the space of 150 years a turbulent and unscrupulous Arrian ecclesiastic should have come to be reputed a holy martyr for the Catholic faith. The caution displayed with regard to St George in the 5th century was not long preserved. Gregory of Tours, for example, asserts that his relics actually existed in the French village of Le Maine, where many miracles were wrought by means of them, and the venerable Bede, while still explaining that the gesta of St George are reckoned apocryphal, commits himself to the statement that the martyr was beheaded under Dacian, king of Persia, whose wife Alexandra, however, adhered to the Catholic faith. The dragon was a still later introduction into the legend, which, as given by Jacobus de Voragine and later writers, ceases to represent the hero as in any sense a sufferer. In its current popular form the story of his successful conflict is probably a mere modification of the old Arrian mythos, to which many interpreters are now disposed to attach a solar interpretation.

The popularity of the name of St George in England dates from the time of Richard Cœur de Lion, who, it was said, had successfully invoked his aid during the first crusade; but it was not till the time of Edward III that he was made patron of the kingdom, although at the council of Oxford in 1222 it had already been ordered that his feast should be kept as a national festival. The republics of Genoa and Venice were also under his protection; and his name is much revered in all the Oriental churches.

See Heylin, *The History of that most famous Saynt and Souilder of Christ Jesus, St. George of Cappadocia* (1631), and Milner, *An Historical and Critical Inquiry into the Existence and Character of St. George, Patron of England* (1795). For some account of the numerous artistic representations, whether of his martyrdom or of his triumph, see Jameson's *Sacred and Legendary Art*, vol. ii.

GEORGE, known as PISIDES or PISIDA, a Byzantine writer of the 7th century, was, as his surname implies, a native of Pisidia; but of his personal history nothing is known except that he had been ordained a deacon, and that he held either simultaneously or successively the offices of "Chartophylax," "Scenophylax," and "Referendarius" in the "Great Church" (that of St Sophia) at Constantinople. He is also believed to have accompanied the first expedition (622) of the emperor Heraclius against the Persians; at all events his earliest work, consisting of 1098 iambic trimeter verses under the title *Εἰς τὴν κατὰ Περσῶν ἐκστράτειαν Ἡρακλείου τοῦ βασιλέως ἀκροαεὶς τρεῖς*, is devoted to such a description of that campaign as could hardly have come from any other than an eye-witness. This composition was followed by the *Ἀβαρικά* or *Πάλεμος Ἀβαρικός* in 541 verses, containing the details of a futile attack on Constantinople made by the Avari in 626, while the emperor was absent and the Persian army in occupation of Chalcedon; and by the *Ἡρακλείς*, a general survey of the exploits both at home and abroad of Heraclius down to the final overthrow of Chosroes in 627, which is believed to have been written before the end of 628. In addition to these three works, which have been edited by Bekker in the *Corpus scriptorum histor. Byzant.* (1836), we have from the pen of

¹ The full text of this canon is given by Heylin, p. ii. c. 9.

George of Pisidia the Ἑξαήμερον ἡτοι Κοσμογονία, a poem upon the creation of the world, containing in its present form 1910 trimeter iambic verses; a treatise on the vanity of life, Ἐπὶ τὸν μάταιον βίον, in 263 verses; a controversial composition against Severus of Antioch, Κατὰ Σεβήρου, in 731 verses; two short poems upon the resurrection of Christ and upon the temple of the Virgin at Blachernæ respectively, and a prose encomium upon Anastasius the martyr, (Ἐγκώμιον εἰς τὸν ἄγιον Αναστάσιον μάρτυρα). George of Pisidia is known to have written several other works, which, however, are no longer extant; and there is no sufficient reason for assigning to him the compilation of the *Chronicon Paschale*, or the astronomical poem entitled *Empedodis Sphæra*. The *Hexameron* and *De Vanitate Vitæ* were first printed along with a Latin version at Paris in 1584 or 1585 by Federicus Morellus. They are also to be found in the *Mus. Bibliotheca Velt. Patrum*, xii. p. 322 (1677), and in the 46th vol. of Migne's *Patrologia Græca*. The only complete edition of all the extant works is that of Quercus in Fogani's *Corp. Hist. Byzant. Nova Appendix* (Rome, 1777). As a versifier George is correct and even elegant; as a chronicler of contemporary events he is exceedingly useful; but the modern verdict on his merits as a poet has not confirmed that of those later Byzantine writers whose enthusiastic admiration led them to compare him with and even prefer him to Euripides. Recent criticism is unanimous in characterizing his composition as artificial and almost uniformly dull.

GEORGE OF TREBIZOND (1396-1486), one of the distinguished writers in the great controversy between Aristotelism and Platonism in the 15th century, was born at Chandaee in the island of Crete. He received his cognomen apparently from the fact that his ancestors had come from Trebizond. At what period he came to Italy is not absolutely certain; according to some accounts he arrived as early as 1430, and settled as teacher of philosophy and rhetoric at Venice; according to others he did not come over to Italy till the period of the council of Florence (1438-9). His reputation as a teacher and as translator of Aristotle was very great, and he was selected as secretary by Pope Nicholas V., an ardent Aristotelian. The needless bitterness of his attacks upon Plato (in the *Comparatio Aristotelis et Platonis*), which drew forth a powerful response from Bessarion (*q.v.*), and the manifestly hurried and inaccurate character of his translations both of Plato and of Aristotle, combined to run his fame as a scholar, and to endanger his position as a teacher of philosophy. The indignation against him on account of his first-named work was so great that he would probably have been compelled to leave Italy, had not Alphonso V. given him protection at the court of Naples. He died at Rome in 1486. Many of his translations of Aristotelian treatises are to be found in the older editions of Aristotle. A notice of his other writings is given in Fabricius, *Biblioth. Græca*.

GEORGETOWN, the port of entry for the District of Columbia in the United States of North America, is situated on the left bank of the Potomac at the head of navigation, about 2½ miles W.N.W. of the capital of Washington City, with which it communicates by four iron bridges thrown across Rock Creek. Founded by the colonial Government of Maryland in 1751, Georgetown was a city with a distinct administration from 1789 to 1871; but in the latter year it was merged in the District of Columbia, and in 1878 it was incorporated with the city of Washington, so that now it has properly no distinct existence. It is beautifully situated along a range of hills, whose loftier eminences, locally called the Heights, afford delightful positions for villas and country seats, with extensive prospects over the river and Washington. The most noteworthy institution is Georgetown College, the oldest Roman Catholic college

in the United States, which occupies two handsome brick buildings in the midst of extensive grounds at the west end. It was founded as an academy in 1789, was chartered as a college in 1799, and in 1815 received the right of conferring degrees. Its medical department, originated in 1851, and the legal department, dating from 1870, are both in Washington. The university has a library of upwards of 30,000 volumes, an extensive apparatus for physical science, and a museum of natural history. In 1873 the teaching staff numbered 35. Among the other institutions in the town may be mentioned the Convent of the Visitation, with a female academy attached; the Peabody library; the Linthicum institute (founded in 1872 by a retired merchant, who left \$50,000 for the education of poor white boys); the aged women's house, maintained by voluntary subscription; and the industrial home for juvenile vagrants. The aqueduct which conveys a branch of the Chesapeake and Ohio canal over the Potomac is 1446 feet long, and its granite piers, nine in number, rise 36 feet above the ordinary surface of the water, and rest on the solid rock 17 feet below the bottom of the river. A great decline has taken place in the commercial activity of Georgetown. Its foreign trade is very slight, being represented in the year ending June 30, 1878, by no more than 6113 dollars of imports and 10,056 dollars of exports; but its share in the coasting trade is still considerable, 187 steamers and 45 sailing vessels, affording a total tonnage of 96,339 tons, having entered in the year already mentioned, its position at the terminus of the Chesapeake and Ohio canal secures for it a fair share in the shipping of the coal from the Alleghany fields; and its fisheries render it a great market for shad and herrings. Among the industrial establishments the first place is held by the flour-mills, six in number; but there are also corn-mills, timberyards, tanneries, foundries, breweries, a paper-mill, and a vinegar factory. The principal cemetery for Washington occupies a beautiful situation on Georgetown Heights. In 1830 the population of Georgetown was 8441; in 1840 it was only 7313; by 1860 it had reached 8733; and in 1870 it was 11,384.

GEORGETOWN, known as Stabroek during the Dutch period, now the capital of British Guiana, is situated in the county of Demerara on the east bank of the Demerara river, about a mile from its mouth, in 6° 49' 30" N. lat. and 58° 11' 30" W. long. It is one of the prettiest towns of that part of the world, and presents an unusually attractive appearance to the approaching voyager. The streets are wide and straight, intersecting each other at right angles, and recalling, by the canals that run along the centre, the memory of the Dutch; and the houses are so richly embosomed by cabbage-palms, cocoa-nut trees, and other trees and shrubs, that they look rather like a collection of villas than a town. The street along the river side, where the shops and stores are mainly situated, forms, however, an exception; there everything is plain, bare, and business-like. Private dwelling-houses are usually built of wood and raised 3 or 4 feet above the soil on wooden piles or brick pillars; they are painted in various simple colours, for the most part in white; in front they have open verandahs. Among the public edifices the first place is due to a building in the centre of the town which was erected between 1829 and 1834 at a cost of £60,000, to accommodate the legislative council, the courts of justice, the custom house, the treasury, and other administrative offices; it is of considerable extent and architectural beauty, with shady porticoes and marble-paved galleries supported on cast-iron columns. Besides a cathedral, which cost £15,000, there are churches belonging to the Wesleyans, the Baptists, the London Missionary Society, and other ecclesiastical organizations, several liberally-maintained hospitals, an leprosy house, and two market-

places, of which the one opened in 1844 cost £11,400, and the other opened in 1852 cost £2450. The prison, a large building, or rather collection of buildings, surrounded by a strong wooden wall, can accommodate upwards of 200 prisoners. A fort, the Frederick William, situated below the town, only contains a small battery, but in the vicinity there are extensive and well-organized barracks. One of the principal disadvantages due to the position of Georgetown is the lack of drinking water, but this is so far remedied by the construction of both private and public tanks for the storage of the rain, by the introduction of water from the Lamaha creek, by a canal, and further by the boring of Artesian wells. The first attempts to apply the Artesian principle was made in 1831 by Major Staple, and his example has been widely imitated not only in the town itself but also in the surrounding country. Though the water thus obtained is strongly impregnated with iron, carbonic acid gas, salt, and magnesia, it is readily drunk by horses and cattle, and after it has been scummed and filtered it can be used for cooking. As it rises to the surface the water has a temperature of 84° Fahr., 5° higher than the water in the river. Ice is almost a necessity of life in the town, and it forms a regular import from Boston, along with fresh meat and other northern produce. The population of Georgetown in 1851 was 23,508; in 1861 it was 29,174; and by 1871 it had reached 36,562. (See Appun, *Unter den Tropen*, Jena, vol. u).

GEORGIA, a kingdom in central Transcaucasia, remarkable for the long list of its sovereigns, the monarchy having extended over a period of upwards of 2000 years, the kings reigning at times independently, or under the rule of Persia, Turkey, or the Eastern empire. The earliest name of the country was Kartli; the ancients knew it as Iberia, bounded on the one side by Colchis and on the other by Albania; and it has for centuries been called Georgia.

Georgia proper, which includes Kartli and Kakhetia, is bounded on the N. by Ossety and Daghestan, on the E. by Shekyn, on the S. by Shamsbadly and the khanates of Erivan and Kars, and on the W. by Gouria and Imeritia; but the kingdom at times included Gouna, Mingrelia, Abkhasia, Imeritia, and Daghestan, and extended from the great mountain range to the Araxes. It now forms the government of Tiflis, divided into the districts of Doushett, Telav, Sygnal, Gori, and Akhalzikh, having an area of nearly 25,000 square miles, and in 1873 a population of 635,313, made up chiefly of Georgians and Armenians,—there being also Persians, Tatars, and a few Jews and Europeans. The chief city is the ancient capital of Tiflis, the seat of government, under a governor-general, for the whole of Transcaucasia, and the principal centre of commerce. See CAUCASUS and TIFLIS.

Vegetable Products.—The valleys and declivities are fertile, producing maize, millet, barley, oats, rice, beans, lentils, and corn (which is best in the plains near Gori), also cotton, flax, and hemp, now exported exclusively to Russia. The vineyards cover 75,400 acres, the average produce of wine being at the rate of 230 gallons per acre, the valley of the Alazan yields the best qualities. It is consumed in the country and adjoining districts, the only wine exported being that produced from vine-canes brought from the Crimea. Grapes are gathered in September, and the wine is fit for use one month after it has been put into a *boudjoul*, "skin," or *kewry*, a huge earthen jar in which it may be preserved for years. New vines are planted every six, eight, or ten years, according to the nature of the soil, and are cut after the fruit is gathered, and again in March and April when the soil is turned up. The *Lecanium vitis* and *Oidium* have attacked the plants from time to time, though not in severe form, but the *Phylloxera vastatrix* has hitherto quite unknown. In the vineyards are often seen

the apple, pear, and quince trees; other fruits include the pomegranate, peach, apricot, plum, almond, mulberry, pistachio, fig, cherry, walnut, hazel-nut, medlar, melon and water melon, raspberry, &c. In summer the banks of streams are covered with beautiful wild flowers,—the primrose in double form, the crocus of varied colours, and snowdrops appearing early in March in the greatest profusion.

Animals.—The domestic animals are the camel, ox, mule, ass, and buffalo as beasts of burden, with the goat, and an immense number of pigs, pork being favourite food. The horse—small, hardy, and enduring—is ridden more frequently unhoused, except in the hills; no pauns are taken to improve the breed. The wild animals of greatest importance are the bear, ibex, wolf, hyena, fox, wild boar, wild goat, and antelope, while the pheasant, woodcock, quail, and "partridge of the Caucasus" are the principal winged game. The fish taken in the Kour and other rivers are the sturgeon, silurus, carp, perch, trout, gudgeon, and a fish resembling the salmon, called *orayola* by the Georgians. The great sturgeon, *belouga* or hansen, is taken at the estuary of the Kour in the Caspian.

Communication.—A railroad connects Tiflis with Poti on the Black Sea, the line over the Souram pass, 3037 feet above the sea, being laid at gradients of 1 in 22, over a distance of about 8 miles. Lines of rail are projected for connecting Vladykavkaz in the north, and Djoulpha in the Persian frontier, with the capital. Post-roads are excellent, and saddle-horses and comfortable vehicles for post-horses are to be obtained at the principal towns. Locomotion is very inexpensive.

History.—The material at the disposal of the historian of Georgia is scanty. An anonymous work of the 12th century gives the history from the earliest times to the year 1124, another, also anonymous, is a continuation to the division of the kingdom in 1446, and a third is the compilation by the Casarevich Wladislaw, being the complete annals from the earliest times to the year 1746. These, and a few pamphlets indifferently edited, if we except the memoirs of his family by Stephen Obeliani, archbishop of Siouny in the 13th century, comprise all that is left to us during an interval of upwards of 2000 years.

The earliest Armenian chronicles have included facts on Georgia, which it is believed were founded on traditions they received from the Georgians. According to these authorities, the Georgian, Armenians, Kakhetians, Lezgians, Mingrelians, and other races in Transcaucasia are the descendants of Thargamos, who was the great-grandson of Japhet, the son of Noah, though we read in Gen. x. 3 that Togarmah was the son of Gomer, who was the son of Japhet. These different populations were afterwards included under the general name of Thargomans. The second son of Thargamos, named Kartlihus, having settled in that part where is now the rivulet Kartli, became the patriarch and king of the people in the land round, called Kartli after himself. His son M'zikhethos founded the city of M'zikhetha, which became the capital, and a son of M'zikhethos, named Onphlis, was the author of the rock-cut town near Gori. At that period the title assumed by the ruler was *nanusakikhye*, "lord or head of the house," the worship being that of the sun, moon, and five planets. The first to receive the title of king was Pharnawaz, 302-237 B.C., who rid the country of the Lyant Ason, a governor appointed by Alexander the Great. Pharnawaz originated the orthography of the Georgian language, and is said to have invented the military alphabet. In 140 B.C. Mirvan became king. His son and successor was dethroned by his own subjects, and the crown offered to Artabanus I., whose son, Arsaces, ascended the throne 71 B.C., the dynasty of Arsaces thus commencing its rule. The deeds of Sulla, Lucullus, Pompey, and Mithradates next serve to illustrate the courage and warlike qualities of the people of Iberia. In 265 the Sassanian dynasty commenced in the person of Mirvan, son of Shapur I., who was married to a daughter of the late king Asphagur. Mirvan and all his subjects were converted to Christianity by Nanna or Nina, a poor captive, who had escaped the persecution of Tiridates, king of Armenia. She prevailed upon the people of Kartli to desist from offering human victims, and to overturn their pagan altars; and the king erected a sanctuary, which was afterwards replaced by a noble edifice, 364-379, on the spot where now stands the cathedral at M'zhetti. Mirvan applied to Constantine for priests to instruct his people, and many were sent, among them being Eustathius of Antioch. In 469 King Yakhtham, surnamed *Gourgasal*, "wolf-lion," founded

a city which he called Tlilyrys-Kakaly, now Tiflis, on account of the warm springs there. Vakhtang established a patriarchate at Mtskheta, and constructed the fortress of Soanum. He conquered Mingrelia, and brought the Ossets and Abkhazians under subjection. He also took possession of a large part of Armenia, and having formed an alliance with Chosroes, king of Persia, even advanced into India. The seat of government was transferred from Mtskheta to Tlilyrys-Kakaly, when Datchy came to the throne in 490. At this epoch the Georgian and Armenian Churches had separated, and a century later, the Georgian and Russian Churches united. On the death of Stephanos, who had ruled under the protection of the Eastern empire, a Bagratide named Gouran was nominated cotruepotate by the emperor. Soon after the appearance of Mahomet in the 7th century, the Arabs, having conquered the Persians, entered Armenia and Georgia, and for nearly a century compelled all, under pain of death, to embrace Mahometanism. In 787 the Sassanian dynasty came to an end. Ashod I., *Mede*, "the Great," a Bagratide, succeeded, receiving from the caliph Hachem al Raschid the title of grand prince, and that of cotruepotate from the emperor, but it was not until about 841 that the sovereign (Bagrat I.) was recognized by the caliph as ruler, the country during the interval having been continually ravaged by the Arabs. Their last expedition, in the reign of Bagrat I., included the occupation of Tiflis. The reign of Bagrat III. marks an epoch, for that monarch, who was king of Abkhazia, succeeded to the crown of Georgia by right of inheritance, his sovereignty extending from the Black Sea to the Caspian. He encouraged the arts and sciences, and was the founder of the noble cathedral at Koutais, the first building in the style of architecture theretofore denominated Georgian. During the reign of Bagrat IV. the Seljuks commenced in 1048 a succession of invasions, until they were effectually repulsed by Liparit Orbeluk at the head of a comparatively small force of Georgians, Armenians, and Greeks. Liparit himself was taken prisoner, and Bagrat carried off his wife in his absence, but, regaining his liberty, Liparit took up arms against his sovereign, and drove him out of his capital into Abkhazia. Bagrat appealing to the emperor, it was arranged that he should retain to his kingdom of Georgia and Abkhazia, Liparit being suffered, as his dutiful subject, to retain the province of Meschia.

In 1064 the Seljuks under Art-Ashlan again overran Georgia, destroying Tiflis and slaughtering the inhabitants. In 1072 George II. ascended the throne, and in his reign Tiflis was again devastated by the Seljuks, the king himself being forced to fly. With his valiant son and successor, David III. the fortress of Georgia changed, for the emperor was driven out of the plains of Kakhetia, and the limit from Tiflis to An was fixed by his presence in 1128 by Ivan Orbelian, whose signal services were rewarded by elevation to the rank of constable. The next monarchs were Demetrius I. and David IV., the latter, at his death, entrusting his son Demna or Demetrius to the guardianship of Ivan Orbelian, and the regency to his brother George, who with the assistance of Ivan, greatly extended the Georgian territory, rescuing from the Seljuks a large portion of Armenia. When in 1177 Demna had attained his majority, the nobles desirous of supporting the young prince's claims called upon Ivan, whose popularity had meanwhile been increasing, to place him on the throne. George fortified himself at Tiflis and awaited events, his rule, however, was too firmly established to be easily shaken, and, many of Ivan's partisans espousing his cause, he at length set out to besiege Lorby, which Ivan and his change had made their headquarters. Numerous desertions reduced the ranks of the besieged, until young Demna fled to Persia to the encouragement of his uncle, and entreated him to spare his life. His prayer was granted, but he was deprived of his eyes, and otherwise mutilated. The prince having surrendered, Ivan declared his readiness to submit on condition that he should be honourably treated. George assented, showed his prisoner all honour until he had got the whole of his relatives into his power, when he ordered that all should be massacred, Ivan himself being blinded and brutally treated. Three only of his kinsmen were saved—a brother named Liparit, and his two sons who had gone to Persia to solicit the aid of the sultan of Ilkizand. From them are descended the Orbelians of the present day. At the time of their extermination, the possessions of the Orbeluk comprised more than the half of Georgia. It is related that the ancestors of this powerful family, princes of the family of Djienkapour of the royal race of Djenesian, first came to Kartli from that part of Asia which lies between China and the Ural; the fortress of Orpeth was given to them for a residence. In return for the friendly reception accorded to them, they united with the Kartliotes in throwing off the Persian yoke, a service which obtained for the chief Orbeluk the rank of *sizer* or *geranissier*. During the reign of Pharnavaz, the Orbeluk took precedence next to the sovereign, and matrimonial alliances were formed with the royal house. The first of the family individualized in the annals was the warrior Liparit (875-900). George III. died in 1184, and was succeeded by his only child Thamar, whose kingdom extended from the Caspian to the Black Sea, and from beyond the Caucasus to Armenia, for

Trebizond, Erzeroun, Tovin, Kars, and An fell to her arms. Her missionaries travelled far and wide, and numerous churches were constructed, and thus it was that her many virtues and brilliant rule secured to her the title of *Mephe*, "king." This great queen was succeeded in 1212-13 by her son George IV., surnamed *Lasha*, "He who enlightens the world," who, assisted by the powerful noble, Ivan Mkhargdeladze, of the family that had replaced the Orbelian in the royal favour, vanquished the Persians in many battles, conquering Gandsa, and permanently occupying Kars. In 1220 and 1222 the Mongols again visited Georgia. The king left an infant son who afterwards reigned as David IV., but his own sister, Bonssoudan, seized the crown in 1228, and passed a life not free from reproach. To revenge himself upon the queen, who refused his suit, Jalal-uddin twice occupied her capital, and her kingdom was again overrun by the Mongols, who committed fearful ravages. Next follow the exploits of Tamar, who invaded Georgia in 1268, and, having seized upon the capital, carried away the king, Bagrat V. who feigned conversion to Islamism that he might gain the confidence of the conqueror. By this means he succeeded in obtaining from Timur a force of 12,000 men, for the purpose of prevailing upon his people to embrace Mahometanism. Bagrat had preconcerted his plans, and in due course every Tatar in his suite was slaughtered by his own warriors. In an ungenerous passion Timur re-entered Georgia (1299-94), and laid waste the entire country, leaving towns and villages without spring of single life. Saturated with bloodshed, he withdrew to the plains of Karabagh, and George VII., son and successor to Bagrat, returned upon the death of his father (1401) from the mountains where he had remained concealed, and occupied the capital. Timur made war upon him as well, compelling his submission, and in 1403 finally quitted the country. George was succeeded by Constantine II., whose successor, Alexander I., son of George VII., restored the kingdom to prosperity, but towards the close of his days he conceived the unhappy idea of dividing his kingdom among his three sons, an act that was followed by intestine wars, rebellions, massacres, and foreign invasions. From about this period commences the relations of Russia with Georgia and its neighbouring principalities, for in 1492, during the war fomented between Turkey and Persia, Alexander, king of Kakhetia, sought the protection of the czar John III. Again, in 1587, Boris Godounoff was appealed to for succour, and when, in 1618, Shah Abbas invaded Georgia, Timouraz I. applied for assistance to Michael Fedorovitch (the first of the Romanoffs), as did also, in 1621, George IV., king of Imeretia, and Michael Fedorovitch, czar of Russia. In 1638 Levon, sovereign of Mingrelia, took the oath of allegiance to Alexis Michaelovitch, and in 1680 Alexander of Imeretia acknowledged the sovereignty of Russia. That empire, however, could not render material assistance to those petty sovereigns in distress, and little was done until fresh excesses committed by the Turks and Persians afforded Peter the Great the excuse for sending an expedition, in 1716, under Bekrevitch a Circassian chieftain, to survey the Caspian shore and erect defences. Bekrevitch was overpowered by the Tatars, and slaughtered with the whole of his force. Peter then occupied the western shore of the Caspian, taking the king of Georgia under his protection. This was Vakhtang VI., the author of a code that was in vogue until 1841, when Russian laws were in great measure introduced. But he was unable to resist Nadir Shah and soliciting in 1724, retired to Ashtarkhan, where he died. Peter being at peace with Turkey, and having concluded the treaty of Nystadt with Sweden, left Moscow, May 21, 1722, and embarked at Ashtarkhan with troops destined for Georgia and the Persian provinces. Derbent, Baku, Gilyan, and Masenderon fell into his power, and he constructed a fort on the ruins of the town, which he named St. George. All these places were ceded by treaty, in 1732, after Nadir Shah had delivered Kartli and Kakhetia from Turkish oppression. A few years later, in 1735, Turkey renounced all claim to those countries in favour of Persia. When war broke out with Turkey in 1768, General Todleben was sent to the assistance of Solomon I., king of Imeretia, and the Turks were expelled that kingdom. Then followed the treaty of Kaimardan in 1744, by which Georgia, Imeretia, and Mingrelia were placed under the protection of Russia. In 1795 Aga Mahomet Shah laid Tiflis in ruins, a disaster that was succeeded by dissensions in the royal family; and Heraclius II., who in 1783 had declared himself the vassal of Russia, now appealed to that country for protection. The next sovereign, George XIII., renewed this appeal, which would have been granted but for the sudden death of the emperor Paul. Alexander I. hesitated for a time, until George finally renounced his crown in 1799 in favour of Russia, drawing down upon him the hatred and curses of his country. His younger brother, Alexander, made an effort to secure the crown, but the chiefs saw the impotence to throw off the Russian yoke, and, being but poorly supported, the prince was beaten on the banks of the Lora. George died the following year, being the last of the Bagratides to occupy the throne of Georgia, which his ancestors had held for the space of 1029 years. It may be stated that the Bagratides claim descent from David, by his adulterous intercourse with the wife of Urnah! Georgia was now virtually annexed to the empire, and on

September 19, 1801, Alexander I. issued a proclamation announcing the fact to the people of that country. In 1810 the prince of Imeritia revolted against Russia; but this movement was quickly suppressed, and the principality annexed. Mama V, the ruler of Gouria, recognized the suzerainty of Russia in the same year, his principality being eventually annexed in 1829.

See Vakhtang, *Histoire de la Géorgie*, trans by Brosset, and additions, 5 vols, St. Petersburg, 1849. Vlad. km. *Sobremennaya Prouslavnyaya na Kavkaze*, Moscow, 1874. *Zhidatse, Otkrytiye Ispytaniya Kavkaza*, Tiflis, 1873, Comm J. Buchan Telfer: R. N. *The Crimea and Transcaucasia*, 1871 (J B TE)

Ethnology.—Of the three main groups into which the Caucasian races are now usually divided, the Georgian is in every respect the most important and interesting. It has accordingly largely occupied the attention of Orientalists almost incessantly from the days of Klaproth to the present time. Yet such are the difficulties connected with the origin and mutual relations of the Caucasian peoples that its affinities are still far from being clearly established. Anton Schaeffer and P. V. Uslar, however, who must be accepted as undoubtedly the greatest authorities on the subject, have at least arrived at some negative conclusions valuable as starting points for further research. In their valuable papers, published in the *Mémoires* of the St Petersburg Imperial Academy of Sciences and elsewhere, they have finally disposed of the views of Bopp and Brosset, who attempted on linguistic grounds to connect the Georgians with the Aryan family. They also clearly show that Max Müller's "Turanian" theory is untenable, and they go a long way towards proving that the Georgian, with all the other Caucasian languages except the Ossetian, forms a distinct linguistic family absolutely independent of all others. This had already been suspected by Klaproth, and as the same conclusion has been arrived at by Fr Müller and Zagarelli, it is not likely to be set aside by further investigation.

Uslar's "Caucasian Family" comprises the following three great divisions—

1. Western Group. Typical races: Tchetchkessians and Abkhassians
2. Eastern Group. Typical races: Tchetchkessians and Lezgians.
3. Southern Group. Typical race Georgians.

Here the term "family" must be taken in a far more elastic sense than when applied, for instance, to the Aryan, Semitic, or Eastern Polynesian groups of mankind. Uslar would, perhaps be the first to admit that the fundamental unity of the three groups has not yet been established, and that they present at least as wide divergences as are found to exist between the Semitic and Hamitic linguistic families, whose primitive relationship has not yet been definitely determined. Thus, while the Abkhassian of group 1 is still at the agglutinating, the Lezgian of group 2 has fairly reached the inflecting state, and the Georgian seems still to waver between the two. In consequence of these divergent stages of development, Uslar hesitates finally to fix the position of Georgian in the family, regarding it as possibly a connecting link between groups 1 and 2, but possibly also radically distinct from both.

Including all its numerous ramifications, the Georgian or southern group occupies the greater part of Transcaucasia, reaching from about the neighbourhood of Batoum on the Euxine eastwards to the Caspian, and merging southwards with the Armenians of Aryan stock. It comprises altogether nine subdivisions, as in the subjoined table—

1. The GEORGIAN PROPER, who are the *Therians* of the ancients and the *Gruga* of the Russians, but who call themselves *Kartlians*, and who in medieval times were masters of the Rion and Upper Kura as far as its junction with the Alazan.
2. The IBERIANS, west of the Saram mountains as far as river Tschouen-Tschali.
3. The GEORGIAN, between the Rion and Lazistan.
4. The LAZES of Lazistan on the Euxine
5. The SWANITIANS, SHAVANS, or SWANIONS, on the Upper Ingur and Tschouen-Tschali rivers.
6. The MINGRELIANS, between rivers Tschouen-Tschali, Rion, Ingur, and the Black Sea.
7. The THERES or MOKHES, {about the headstreams of the Alazan and
8. The PSHAYS or PSHITZAY, {
9. The KHEVURUS, { Jura rivers

All these formed jointly the ancient kingdom of Iberia, whose *metropolis* or "king" resided at Mzketht till 469 A.D., when the seat of government was removed to the neighbouring Tbilissi or Phyliss-kiaht, i.e., "warm town," so called from its thermal springs. This place has ever since continued to be the capital of the kingdom, and now bears the abbreviated name of Tiflis. The representative branch of the race have always been the Kartlians, a name which the native Christian chroniclers profess to trace back to Kharthos, second son of Thargamos, son of Japhet, son of Noah. From Thargamos all their tribes are by their writers called, collectively, Thargamosians, and from Kharthos their country receives the name of Kartveli or Kartli. But no weight can be attached to these genealogies and etymologies, which would doubtless never have been heard of but for the national desire to connect the race with the Mosiac account of the dispersion. It is now pretty well established that the Georgians are the descendants of the aborigines of the Pamakhi highlands, and that they found their way to their present homes from the south-east some four or five thousand years

ago, possibly under pressure from the great waves of Aryan migration flowing from the Eranian table-land westwards to Asia Minor and Europe. The *Therians* Georgian and Gysay are simply corruptions of the Persian *Gurjan*, as in Gurjistan-Gurjarland-Georgia. The Georgians proper are limited on the east by the Alazan, on the north by the Caucasus, on the west by the Meskhiian hills, separating them from the Imeritians, and on the south by the Kur river and the Kairadagh and the Pamakhi mountains. Southwards, however, no hard and fast ethnical line can be drawn, for even immediately south of Tiflis, Georgian, Armenians, and Tatars are found intermingled confusedly together.

The Georgian race, which represents the oldest elements of civilization in the Caucasus, is distinguished by some excellent mental qualities, and is especially noted for personal courage and a passionate love of music. The people, however, are described as fierce and cruel, and addicted to the vice of intemperance, though Von Thielmann speaks of them as "rather hard drinkers than drunkards." Physically they are a fine athletic race of pure Caucasian type; hence during the Moslem ascendancy Georgia supplied, next to Circassia, the largest number of female slaves for the Turkish harems and of recruits for the Osmanli armies, more especially for the select corps of the famous Mameluks.

The social organization rested on a highly aristocratic basis, and the lowest classes were separated by several grades of vassalage from the highest. But since their incorporation with the Russian empire, these relations have become greatly modified, and a more sharply defined middle class of merchants, traders, and artisans has been developed. The power of life and death, formerly claimed and freely exercised by the nobles over their serfs, has also been expressly abolished. They are altogether at present in a fairly well-to-do condition, and it cannot be denied that under the Russian administration they have become industrious, and have made considerable moral and material progress.

Missionaries sent by Constantine the Great introduced Christianity about the beginning of the 4th century. Their efforts were greatly aided by the exemplary life of a female slave named Nina, who came into Georgia during the reign of King Miran (265-318), and who occupies a prominent place in the ecclesiastical records of the country. Since that time the people have, under severe pressure from strict and Mahomedan communities, remained faithful to the principles of Christianity, and are still amongst the most devoted adherents of the orthodox Greek Church. Indeed it was their attachment to the national religion that caused them to call in the aid of the Christian Muscovites against the proselytizing attempts of the Shiite Persians—a step which ultimately brought about their political extinction.

As already stated, the Kartli language is not only fundamentally distinct from the Aryan linguistic family, but cannot be shown to possess any clearly ascertained affinities with either of the two northern Caucasian groups. It resembles them chiefly in its phonetic system, so that according to Rosen (*Symplexe der Laenen*) all the languages of central and western Caucasus might be adequately rendered by the Georgian alphabet. Though certainly not so harsh as the Avar, Serghian, and other Daghestan languages, it is very far from being euphonic, and the frequent recurrence of such sounds as *ts, ds, ths, kh, khl, gh* (Arab. ج , د , ث) for all of which there are distinct characters, renders its articulation rather more energetic and rugged than is agreeable to ears accustomed to the softer tones of the Eranian and western Aryan tongues. It presents great facilities for composition, the laws of which are very regular. Its peculiar morphology, standing midway between agglutination and true inflexion, is well illustrated by its simple declension common to noun, adjective, and pronoun, and its more intricate verbal conjugation. As to personal endings, seven tenses, and incorporation of pronominal subject and object, all showing decided progress towards the inflecting structure of the Aryan and Semitic tongues.

Georgian is written in a native alphabet obviously based on the Armenian, and like it attributed to St Mesropous (Mesrob), who flourished in the 6th century. Of this alphabet there are two forms, differing so greatly in outline and even in the number of the letters that they might almost be regarded as two distinct alphabetic systems. The first and oldest, used exclusively in the Bible and liturgical works, is the square or monumental *Khuduri*, i.e., "sacred," consisting of 38 letters, approaching the Armenian in appearance. The second is the *Alphabetsi khali*, i.e., "soldier's hand," used in ordinary writing, and consisting of 40 letters, neatly shaped and full of curves, hence at first sight not unlike the modern Burmese form of the Palli.

Of the Kartli language there are several varieties; and, besides those comprised in the above table, mention should be made of the Kakhetian current in the historic province of Kakhetia. A distinction is sometimes drawn between the Kartlians proper and the Kakhetians, but it rests on a purely political basis, having originated with the partition in 1424 of the ancient Iberian estates into the three new kingdoms of Kartalinia, Kakhetia, and Imeritia. On the other hand, both the Laz of Lazistan and the Swan pro-

sent such serious structural and verbal differences from the common type that they seem to stand rather in the relation of sister tongues than of dialects to the Georgian proper. All derive obviously from a common source, but have been developed independently of each other. The *Tush* or *Mosch* appears to be fundamentally a Kistian or Tchetschenian idiom affected by Georgian influences.

The Bible is said to have been translated into Georgian as early as the 5th century. The extant version, however, dates only from the 8th century, and is attributed to St. Kuthymus. But even so, it is far the most ancient work known to exist in the language. Next in importance is, perhaps, the curious poem entitled *The Amours of Turul and Nestan Dargan*, or *The man clothed in the panther's skin*, attributed to Rustaveli, who lived during the prosperous reign of Queen Tamar (11th century). Prince Leonidze of Akhmeti in Kakhetia showed Baron von Thielmann a rare and very old MS. of this poem, written on fine hemp paper in exquisite Mikhedruli characters, and embellished with arabesques and miniatures evidently the work of an eminent artist. Other noteworthy compositions are the national epics of the *Baransians* and the *Zostomans*, and the prose romances of *Varamians* and *Dargiamani*, the former by Saig of Tmogvi, the latter by Mosa of Khoni. Apart from these, the great bulk of Georgian literature consists of ecclesiastical writings, hymns sacred and profane, national codes, and chronicles.

See Baron von Thielmann's *Donkey in the Caucasus*, *Peters*, and *Parley to Asia*, translated by the Hon. George London 1878; Fr. Müller's *Bühne geographie und Reise der Ost. Freigabe Novara*, Vienna, 1868; Anton Schiefner and Genes R. V. Uster, numerous papers in the Bulletin of the Académie Impériale des Sciences de Saint Pétersbourg for 1860, &c.; N. Zupatze's *Strassen der la littérature relative à la géographie*, Apollon, St. Pétersbourg, 1873; Michel Smirnov's paper in *Revue d'Anthropologie*, April 16, 1878. (A. H. K.)

GEORGIA*

ITS HISTORY, CONDITION, AND RESOURCES. WITH MAP.

Copyright, 1879, by Charles Scribner's Sons.

*Note III.

GEORGIA, one of the thirteen original States of the American Union, has Tennessee and North Carolina on the N., South Carolina and the Atlantic Ocean on the E., Florida S., and Alabama W. The Savannah river separates the State on the E. from South Carolina; the St. Mary's, on the S., divides it in part from Florida; the Chattahoochee, on the W., flows between Georgia and Alabama for nearly half its course. Georgia lies between 30° 21' 39" and 35° N. lat., and between 81° and 85° 53' 35" W. long. It is 320 miles long from N. to S., and 256 miles in its greatest breadth from E. to W., with an area of 58,000 square miles.

Surface.—Georgia has three distinctly marked zones, varying in soil, climate, and productions. Her sea-coast is similar to that of the Carolinas, being skirted by fertile islands, separated from the mainland by narrow lagoons or by sounds. This section is essentially tropical. Beginning at the sea-coast, a gradually ascending sandy plain extends northward and westward as far as the head of navigation on the Savannah, Ogeechee, Oconee, and Ocmulgee rivers, where it meets a Primary formation. Augusta, Milledgeville, and Macon indicate the northern limit of this tract. Here begins the hilly and finally mountainous region, the most extensive, fertile, and salubrious of the State. A second plateau, 60 or 70 miles broad, stretches above the falls of the rivers until it meets the southernmost ranges of the great Appalachian chain of mountains which traverses Virginia, North Carolina, and northern Georgia under the name of the Blue Ridge, and is finally lost in Alabama. This picturesque district extends in Georgia from Rabun county in the north-east corner of the State to Dade in the extreme north-west, where the summit of Lookout Mountain dominates the valley of the Tennessee. Here are the sources of the two principal rivers of the State; here is the gold-producing region; and here is also the theatre of some of the most sanguinary battles of the civil war. The elevations of the Blue Ridge vary from 1200 to 4000 feet. In the south-east of the State is the extensive Okefenokee swamp, which has an estimated circumference of 180 miles,

is filled with pools and islands, and is the congenial home of alligators, lizards, and other reptiles.

Rivers and Harbours.—There are many fine rivers in Georgia. A north and south line passing through Macon would nearly divide the streams flowing into the Atlantic from those discharging into the Gulf of Mexico. The Savannah, Ogeechee, Altamaha, Santilla, and St. Mary's fall into the Atlantic, and the Chattahoochee, Flint, and tributaries of the Suwanee flow to the Gulf coast. The rivers are generally navigable for steamboats to the falls which occur on the great central plateau of the State—that is to say, the Savannah to Augusta, the Oconee and Ocmulgee (confluents of the Altamaha) to Milledgeville and Macon, and the Chattahoochee to Columbus. Besides their ordinary purposes as avenues of travel and commerce, her rivers have given to Georgia the character of a manufacturing State, and she is developing and increasing their abundant water-powers with energy and success.

The Savannah is formed of two small streams which rise near the North Carolina line, and unite on the boundary between S. Carolina and Georgia in Hart county. Flowing thence in a nearly S.E. direction for 450 miles, it enters the Atlantic near 32° N. lat. The Savannah is navigable from November to June. Ships ascend it 18 miles to the city of Savannah, steamboats to Augusta, 230 miles, and by means of a canal around the falls there, constructed in 1845, light draught vessels navigate it 150 miles higher. This canal, 9 miles long, furnishes the water-power of Augusta. The river is about 800 yards wide. From Augusta the traveller descends the Savannah through the cotton-fields of the table-lands, and the long reaches of semi-tropical vegetation dominated by groves of live oak, to the rich rice plantations of the seaboard.

The Chattahoochee is one of the largest and most interesting rivers of Georgia. It rises on the declivity of the Blue Ridge, in Habersham county, in the N.E. of the State, pursues a devious S.W. course through the gold region of upper Georgia until it reaches West Point, on the Alabama frontier. It then flows nearly south to the Florida State line, where it is joined by the Flint, when the two streams flow on through Florida to the Gulf under the name of the Apalachicola. Large steamboats ascend the Chattahoochee in the season of navigation to Columbus, 350 miles from the Gulf. The whole estimated length of the river is 550 miles. The falls at Columbus create a valuable water-power, constituting that city one of the three important manufacturing centres of the State. Just above Columbus the Chattahoochee is broken in picturesque rapids, overlooked by a rocky cliff called the "Lover's Leap," which is the subject of an interesting legend. Besides Columbus, the towns of West Point and Fort Gaines are the most important on the Chattahoochee in Georgia; Apalachicola at its embouchure on the Gulf is its shipping and distributing port, but is decreasing in importance since the railway system of the State has assumed a large share of the traffic once confined to the navigable streams.

The Oconee and Ocmulgee rise near each other, in the N. of the State, flow through its centre to within 100 miles of the sea, when their united streams pass on S.E. to the Atlantic under the name of the Altamaha. Milledgeville, the former capital of Georgia, is on the Oconee, and Macon on the Ocmulgee. Thence on the Altamaha is reached by vessels drawing 12 to 14 feet of water. The Ogeechee, rising also in the north, is about 200 miles long. It divides the country between the Savannah and Altamaha, entering the Atlantic a few miles south of the Savannah. The Ogeechee is navigable for light vessels 30 or 40 miles, and for keel-boats to Louisville. The Santilla and St. Mary's drain the south-eastern counties, and are each navigable 30 or 40 miles for sloops. The Flint, Ocklawaha, and Suwanee drain the south-western counties; the Flint is navigable to Albany, 250 miles from the Gulf, for steamboats. The Tallapoosa and Coosa, head-waters of the Alabama, and the Hiwassee, one of the sources of the Tennessee, rise in the mountains of Georgia—the last, however, finding its way to the Gulf of Mexico by the Ohio and Mississippi valleys.

Georgia has about 128 miles of sea-coast, but has few good harbours, except within the rivers emptying upon it. St. Mary's, Brunswick, Darien, and Savannah are the principal. The chain of islands lying off the mainland produces the celebrated Sea-island cotton, but owing to the changes brought about by the secession war it is now little cultivated. These islands are flat, and generally little elevated above the sea. Cumberland island, one of the most attractive, is nearly 30 miles long. It is covered with magnificent forests of oak, and its shores are skirted with palms,

* This is reprinted here, with the consent of Messrs Charles Scribner's Sons, of New York, from their work entitled *Georgia: its History, Condition, and Resources*, by Samuel A. Drake. With Map. New York, 1879. Copyright, 1879, by Charles Scribner's Sons.

palmettos, and tropical shrubbery. Other islands from S. to N. are Jekyll, St Simon's, Sapello, St Catharine's, Ossabaw, and Cabbage. The Sea Islands, with the main shore, constitute a coast of 480 miles. St Andrew's, St Simon's, Altamaha, Doboy, Sapello, St Catharine's, and Ossabaw are the principal sounds.

Climate, Soil, and Productions.—The central and southern portions of Georgia, including the seaboard, are subject to excessive heats in summer. At Savannah observations show the mean temperature for July to have sometimes reached 99° Fahr. In the northern district of the State the same season is cooler and less enervating. Indeed, the mountain region is becoming noted for its genial and healthful climate, and is attracting invalids and pleasure seekers from all parts of the Union. In the low marshy lands lying contiguous to or upon the coast, malarious fevers prevail in spring and summer. The belt of country stretching from Augusta across the State to Columbus, having a width of from 30 to 60 miles, is pronounced a very healthy district. At Augusta the mean summer temperature is about 79°, the winter 47°. At Atlanta careful observations give the average of summer heat as 75°, and winter 45°. Diseases of the respiratory organs are rare among natives of northern and central Georgia. The interior is comparatively free from the dreaded epidemics cholera and yellow fever, but Savannah and the coast are periodically scourged by them.

There is in Georgia as great diversity of soil as of climate. Beginning with the Sea Islands, which are composed of a sandy alluvium, intermixed with decomposed coral, we pass from the rich alluvions near the coast, in which the great rice plantations are, to the thinner soil of the Pine Belt, sometimes inaptly denominated Pine Barrens. These are at present valuable for their timber and naval stores, but are susceptible of cultivation. The middle region consists of a red loam, once productive, but from long cultivation impoverished. With the aid of fertilizers it produces cotton, tobacco, and the cereals. We now reach the so-called Cherokee country of the north, containing lands among the most fertile in the State, lands which, notwithstanding their tillage from an unknown period by the aboriginal inhabitants, grow wheat, corn, Irish potatoes, pease, beans, &c., abundantly. Cotton may also be successfully cultivated, but with less advantage than in other districts of the State. This fibre is chiefly produced along the fertile bottom-lands or contiguous uplands of the rivers. The same lands yield rice, Indian corn, and sugar. Middle and south-west Georgia are the most productive cotton regions. In the south-west the soil, though light and sandy, produces cotton. In southern Georgia there are millions of acres of magnificent yellow pine forests of great value for house or ship-building, and in these forests turpentine plantations have been opened. The live-oak, also valuable for ship-building purposes, abounds in the south-east of the State. The swamps afford cedar and cypress, the central region oak and hickory. Walnut, chestnut, ash, gum, magnolia, poplar, sycamore, beech, elm, maple, fir, and spruce trees are found in different localities; but in the older settled districts the original forests have disappeared.

It is frequently said that there is nothing grown in any of the States except Florida that Georgia cannot profitably produce. A few of the tropical fruits of Florida cannot be raised in Georgia, but all those of the temperate zone succeed well. Tobacco may be grown in any part of the State, although it is not extensively cultivated for export. Cotton is the great crop of Georgia. She ranks third among the eight cotton States, having exported or consumed in her own manufactures, for the year ending September 1878, 604,676 bales, worth at the point of export \$30,000,000. Of this crop 3608 bales is classed as Sea-island. Her

crop for 1877 was 491,800 bales. The counties of Burke, Dougherty, Lee, Monroe, Stewart, Sumter, and Washington yield 25 per cent. of the whole product of the State.

The emancipation of the slaves in the Southern States has naturally produced great and important changes in the labour system of that section. The planter must now purchase the labour he formerly owned. The black is free to dispose of his labour to the best advantage. The contracts for labour are of three kinds,—for money wages by the month or year, for a share of the crop, or for specific rent in money or products. The first has been practised to a limited extent by the best and most prosperous planters. The share system has been the one generally adopted, because the blacks greatly affected quasi-proprietorship of the soil, and because the owners were inexperienced in the management of free labour, and not inclined to come personally in contact with it. The share varies in different localities, but usually one-third to half the crop goes to the labourers, the landlords furnishing the necessary tools. The readjustment of labour in the south is watched with the keenest interest in other sections of the Union as one of the difficult problems growing out of the suddenly changed relation between white and black; and though some traces of his original servitude remain a cause of irritation between North and South, the agreement between the enfranchised black and his late master is likely to be harmonious, where each is so dependent on the other as is the case in the cotton-growing States of the Union.

Statistics.—A carefully tabulated statement shows that, in addition to her cotton crop, Georgia produced, in 1876, 28,629,000 bushels of Indian corn, valued at \$14,172,000; 2,840,000 bushels of wheat, worth \$3,895,600, 5,700,000 bushels of oats, worth \$3,876,000, and 23,600 tons of hay, worth \$347,628. To these principal crops should be added the timber and naval stores exported from Atlantic out-ports. In January 1877 there were in Georgia 118,300 horses, 404,900 oxen and other cattle, 99,200 mules, 270,400 milch cows, 378,800 sheep, and 1,458,100 swine, giving a total value of \$80,815,117. The State is admirably adapted for stock-raising, but, as cotton culture offers the quickest returns, it has hitherto engrossed the attention of planters and farmers. The grain and root crops are largely cultivated for the support of the agricultural population.

The rice crop of Georgia in 1870 was 22,277,386 lb; toluacco, 288,596 lb, molasses, 553,192 gals; wine, 21,927 gals; sugar, 644 hds; sweet potatoes, 2,621,562 bush; Irish potatoes, 197,101 bush; butter, 4,499,572 lb; honey, 610,877 lb; wool, 846,947 lb, increased in 1878 to about 1,000,000 lb. The latest official census shows that 6,831,856 acres, valued at \$94,559,468, are improved in farms; value of farm implements and machinery, \$4,614,701; estimated value of all farm products, \$80,820,228; estimated value of manufactured products, \$31,196,115. The total valuation of the State in 1870 was \$268,169,207, against \$645,895,287 in 1860. The decrease is owing to the emancipation of the slaves; but the State is steadily gaining ground in increased acreage cultivated, increased number and value of manufactures, and increased productive capacity everywhere.

Mineral products.—Georgia was perhaps the El Dorado of which the Spaniards who invaded Florida were in search. Before the gold discovery in California, the "placers" of northern Georgia were profitably worked for many years; but since 1852 their produce has almost wholly ceased. The gold-bearing region is comprised in the counties of Lumpkin, Habersham, Forsyth, and Hall,—the precious metal being found in the alluvial deposits of the streams, and also intermixed with the quartz rock of the hills. A branch mint was established by the Government at Dahlonega, the chief town of Lumpkin county. In 1869 it coined gold bullion of nearly half a million dollars' value; but, as in California, the placers, or surface deposits, have become exhausted. Besides this precious metal, Georgia contains, mainly in N.E. or Cherokee Georgia, coal and fossiliferous iron ore distributed along the ridges between the Tennessee and Alabama border. The Cohutta mountains contain copper, and also silver and lead ores. Iron ore, manganese, slate, baryta, and brown hematite are found on the western declivity of this range. Between the Cohutta mountains and the Blue Ridge is a vein of marble, and adjacent to it are the gold-bearing schists, which reappear on the south side of the Blue Ridge. Other minerals are granite, gypsum, limestone, scapolite, marl, burrstone, soapstone, asbestos, shales, trypsil, fluor-spar, kaolin, porcelain clay, arragonite, tourmaline, emerald, carnelian, ruby, opal, calcadony, agate, amethyst, jasper, garnets, schorl, micron rose-quartz, beryl, and even diamonds.

Population.—The latest official census of Georgia (1870) gives a population of 1,184,709 souls, 638,926 being white and 545,142, or nearly one half, black. This population is distributed among 136 counties, which include 8 cities and 134 incorporated towns. Georgia, which ranks tenth in area, is the twelfth of the Union in respect to population. Though showing an increase of 127,423 persons in the previous decade, which embraced the period of the war with the North, she has fallen behind one in her rank, but indications of prosperity in her agricultural and manufacturing interests warrant the belief that Georgia will show a marked gain in 1880. A large proportion of this anticipated increase may be confidently assigned to the northern section of the State, though the middle section is at present most thickly settled.

Counties.—There are 136 counties in the State, viz.—Appling, Baker, Baldwin, Banks, Bartow, Berrien, Bibb, Brooks, Bryan, Bullock, Burke, Butts, Calhoun, Campbell, Camden, Carroll, Cass, Catosa, Charlton, Chatham, Chattahoochee, Chattooga, Clinch, Cherokee, Clay, Clayton, Clinch, Cobb, Coffee, Colquitt, Columbia, Cowetta, Crawford, Dade, Dawson, Decatur, De Kalb, Dodge, Dooley, Dougherty, Douglas, Early, Echols, Effingham, Elbert, Emanuel, Fannin, Fayette, Floyd, Forsyth, Franklin, Fulton, Gilmer, Glascock, Glynn, Gordon, Greene, Gwinnett, Habersham, Hall, Hancock, Harlison, Harris, Hart, Heard, Henry, Houston, Irwin, Jackson, Jasper, Jefferson, Johnson, Jones, Laurens, Lee, Liberty, Lincoln, Lowndes, Lumpkin, Macon, Madison, Marion, McDuffie, McIntosh, Meriwether, Miller, Milton, Mitchell, Monroe, Montgomery, Morgan, Murray, Muscogee, Newton, Oglethorpe, Paulding, Peckens, Pierce, Polk, Polk, Folsom, Putnam, Rabun, Randolph, Richmond, Rockdale, Schley, Sevier, Spalding, Stewart, Sumter, Talbot, Taliaferro, Tatnall, Taylor, Telfair, Terrell, Thomas, Toombs, Troup, Twiggs, Union, Upson, Walker, Walton, Ware, Warren, Washington, Wayne, Webster, White, Whitfield, Wilcox, Wilkes, Wilkinson, and Worth.

Cities and Towns.—Georgia has no large cities. Savannah, the chief sea-port, has a population of about 30,000; Atlanta, the capital, 35,000; Augusta, 23,735; Macon, 10,910; Columbus, 7401; Athens, 4251; Milledgeville, 2750; and Rome, 2748. The important towns are Albany, Americus, Bainbridge, Brunswick, Cartersville, Cornington, Cuthbert, Dalton, Dawson, Eatonton, Fort Valley, Griffin, La Grange, Marietta, Newnan, Thomasville, Valdosta, Washington, and West Point. Columbus, Americus, Atlanta, and Rome, as well as Savannah, are considerable shipping points, for cotton. Athens is the seat of the university of Georgia. Augusta and Columbus are manufacturing centres; Macon has three religious colleges; Dalton, Brunswick, and St. Marys are important export lumber. Andersonville, in Sumter county, acquired terrible celebrity during the civil war as the site of the chief military prison of the Southern Confederacy. Atlanta is by far the best example of rapid growth the State affords. From a population of 21,189 exhibited by the census of 1870 the city advanced to 35,000 in 1876. It is a railway and manufacturing centre. In the vicinity and for its possession were conducted some of the most important military operations of the secession war.

Manufactures.—Georgia is the foremost southern State in her railway and manufacturing enterprises. Both have been chiefly developed since the war, from which everything in the south of the Union dates. Her rivers and railways afford abundant facilities for the movement of merchandises as well as crops. Her streams also provide excellent and unfailing water-power. In the development of her industries a great future is predicted for Georgia. Indeed some of the more sanguine claim that she is already becoming a formidable rival of New England in the manufacture of cotton and woolen fabrics.

There are in the State 83 cotton factories, with 132,238 spindles and 2125 looms. There are 14 woolen factories, with 4200 spindles and 136 looms. Augusta and Columbus take the lead in the number and capacity of these works, for which certain important advantages are claimed. The water-power is so ample that the mills are run by it alone. The streams do not freeze in winter. The cotton and wool are grown at the factory door, saving to the mill-owner the cost of transporting his raw material from a great distance. Labour is cheaper. Finally, the State in order to encourage the investment of foreign capital in manufactures, has by law exempted such capital from taxation for ten years. The product of the Georgia mills finds a ready market in the Southern and Western States. It is asserted on good authority that during the years 1875, 1876, and 1877—years of unparalleled depression to the manufacturing interests of the United States—the mills of Georgia, especially those of Augusta and Columbus, were never idle, and paid a handsome return on their invested capital. Besides the 52 factories which convert so large a share of her raw produce into cloth, there are 1375 grain mills, having 1453 run of stones for corn and 556 for wheat. There are 734 sawmills, 77 wagon and carriage factories, 6 iron-furnaces, 7 iron-foundries, 11 limekilns, 4 potteries, 68 tanneries, 6 turpentine-distilleries, 2 rolling-mills, 6 paper-mills, 12 furniture manufactories, 3 rice-mills, &c. The manufacture of rope, bagging, twine, tobacco, ice, shales and bluffs, agricultural implements, boilers and

machinery, fertilizers, &c., is carried on more or less extensively. Besides Augusta and Columbus, the largest manufacturing city of the State, there are cotton factories at Athens, Macon, West Point, Decatur, and Atlanta. The latter city also has large iron works. Thomasville, Dalton, Albany, Marietta, and Rome are also manufacturing points.

Commerce.—Large vessels can enter only four harbours, viz., Savannah, Dalton, Brunswick, and St. Marys. The inlets or sounds which divide the coast islands from each other or from the mainland are generally only navigable for small craft. At mean low tides the bar of the Savannah (Tybee entrance) has 19, the Altamaha 14, that of St. Marys' sound (entrance to Brunswick) 17, and that of St. Marys' river 14 feet of water. Savannah, Brunswick, and St. Marys are ports of entry. Cotton and lumber are the principal exports. Of the former 610,419 bales of Upland, and 11,309 of Sea-Island were exported during the year ending September 2, 1878. The shipment of wool for the same time was 983,359 lb. These figures should not be taken to represent the crop of the State. The ship-timber, boards, deals, clapboards, &c., are chiefly shipped from the other ports. About 100 vessels, of 23,000 tons burden, are employed in the foreign and coastwise trade. For the year ending December 31, 1878, the total tonnage of the port of Savannah was—Entered, 280,995 tons foreign and 355,532 coastwise; cleared, 223,885 foreign and 418,953 coastwise; value of imports \$505,599, and of exports \$24,014,535. In the district of Brunswick and the district of Brunswick the value of exports was 124,771 and the clearances 32,579 tons; value of exports \$1,030,943. The St. Marys' entries were 16,052 tons foreign and 30,065 coastwise; value of exports \$120,186, and of imports \$1421.

Railways.—Atlanta, Columbus, Macon, Albany, and Augusta are railway centres. In 1860 there were in Georgia 1404 miles of completed railway; in 1878 there are 2340 miles. The Atlantic and Gulf Railway crosses the State from Savannah to Bainbridge, in the extreme south-west, on the Flint river. It is 236 miles long, passing through Blackshear, Valdosta, and Thomasville (from which there is a branch line to Albany—58 miles—and Macon), while from Dupont there is a junction with the Florida lines. The Brunswick and Albany also extends from the coast at Brunswick to Albany, 172 miles, whence it is to be continued in a westerly direction to the Chattahoochee, in Early county. A third line connects Brunswick with Macon (187 miles); and another, the Central Georgia, unites Savannah with Macon and Atlanta (234 miles). The Central Georgia works a branch-line from Macon to Augusta; the Milledgeville and Eatonton from Gordon to Eatonton (22 miles); the South-Western from Macon to Euflala, Ala. (144 miles), with branches from Fort Valley to Columbus (73 miles), Smithville to Albany (234 miles), Cuthbert to Fort Gaines (20 miles), Fort Valley to Perry (13 miles), and Albany to Aikington (36 miles); the Macon and Western from Macon to Atlanta; and the Upson County line from Barnesville to Thomaston (16 miles).

Atlanta is situated on the great iron high-ways from Dowdon, New York, and Philadelphia to Mobile and New Orleans, and from Chicago to Florida. The Western and Atlantic connects Atlanta and the Georgia system with the Tennessee lines at Chattanooga (138 miles). Several great battles were fought for the possession of this railway during the secession war. The Atlanta and Charlotte Air Line extends to Charlotte, N.C. (369 miles). The Georgia railway connects Atlanta with Augusta (171 miles), with lateral lines from Carnak to Warrenton (4 miles), Union Point to Athens (40 miles), and Barnes to Washington (18 miles); it also works the Macon and Augusta line from Carnak to Augusta (70 miles). The Atlanta and West Point (80 miles) unites those places. The Alabama and Chattanooga crosses the N.W. corner of the State. The Cherokee extends from Cartersville on the Western and Atlantic to Rockmart (22 miles). The Columbus and Atlanta, projected between Columbus and Rome, the Memphis branch (Rome to Decatur, Ala.), and Savannah, Griffin, and N. Alabama, from Griffin to Newnan, to be extended to Greenville, Ala., are in progress. The Georgia Southern extends from Dalton to the Ala. State line, portions of Selma, Rome, and Dalton roads, North-Eastern from Athens to Lulu, (39 miles), Ocmulgee and Horse Creek (7 miles); Rome Railroad, Rome to Kingsdon (20 miles).

Government.—The executive power is vested in a governor elected for four years by a majority of the people. If there is no election by the people, the general assembly chooses one of the two receiving the highest number of votes. The legislative authority is conferred upon a senate, members of which are elected for four years, and a house of representatives elected for two years. The legislature holds annual sessions, beginning on the second Wednesday of January. The State judiciary consists of a supreme court of three judges, who hold office for twelve years, one retiring every four years, and of inferior courts, presided over by nineteen judges, appointed by the executive with the consent of the senate. Except in probate cases, these courts have original jurisdiction, civil and criminal, in law and equity. County courts are established in most of the counties. There is an ordinary for each county elected for four years, who holds a court of

ordinary and prolate. The organic law of the State now forbids slavery or involuntary servitude except for the punishment of crime. Imprisonment for debt, and legislation affecting the free exercise of that personal property guaranteed to the citizen by the amendments to the constitution of the United States, are also prohibited. All male inhabitants between eighteen and forty-five are subject to military duty.

There is a homestead exemption of \$2000 on real and \$1000 on personal property, except for taxes, for money borrowed or expended on the homestead, or for labour or materials used upon it. The property held by a married woman at the time of marriage, or subsequently inherited or acquired by her, is not liable for the husband's debts. A married woman may also sue and be sued in matters pertaining to her separate estate, and may carry on trade as if single. Georgia is entitled to seven representatives and two senators in Congress.

Education—Previous to the war, there was no common school system in Georgia. Although a plan of public instruction was organized at an earlier date, it was not given effect until 1873. In that year the schools were put in working condition, and are now to be found in every county of the State. The attendance in 1876 was—whites 121,418, coloured 57,987, showing a small but steady increase for the three years the schools had been in operation. It is computed by the school commission at 200,000 for 1879. The higher branches of education are well represented. As early as 1801 steps for founding a university were taken at Athens. The first commencement took place in 1804. The college proper (Franklin College at Athens) annually admits free of charge "fifty meritorious young men of limited means," and also such as may be studying for the ministry who read aid. There is also connected with the university a medical college, located at Augusta, and an agricultural college at Dahlonega, with nearly 250 students, whose tuition is free. The State college of agriculture and mechanic arts, also connected with the university, has a special endowment derived from the United States of \$240,000; the whole endowment of the university is \$376,500. The university, exclusive of its establishments at Augusta and Dahlonega, has five departments, 18 professors, and 200 students, with a library of 14,000 volumes, and two literary societies. Besides the usual collegiate course, there are a preparatory school and a law school. Mercer College, at Macon, is a Baptist institution. It was founded in 1838, and until 1870 it was located at Penfield, in Greene county. It has an endowment of \$150,000, a library of 12,000 volumes, and about 135 students. Besides the regular academic course, there are schools of law and theology. The high schools at Penfield and Dalton are connected with this college. Emory College at Oxford, Newton county, was chartered in 1836. It is the property of the Georgia and Florida conferences of the Methodist Episcopal Church (South). The present number of students is 156. Emory has a valuable college apparatus and a good working library, but lacks an endowment. The Wesleyan Female College at Macon was one of the first female colleges, if not the first, in the world, its charter having been granted in 1836. It has 200 students, and is the property of the Methodist denomination. Since 1840 degrees have been conferred upon 1080 graduates. The Southern Missions Female College at Covington belongs to the Grand Lodge of Georgia, and is designed to educate female orphans of freemen. Pico Nono College at Macon is a recently established Catholic institution, chiefly founded by the efforts of the bishop of Savannah. The Atlanta University for the education of negroes was established by the now extinct Freedmen's Bureau and various charitable societies of the Northern States. It receives an annual appropriation from the Georgia Legislature of \$8000. It accommodates 240 pupils. There are a number of institutions, in addition to those enumerated, that are entitled colleges, but come more properly within the designation of high schools. There are also institutions for the blind (at Macon), and for the deaf and dumb (near Rome).

Objects of Interest.—Perhaps the most beautiful scenery in Georgia is to be found in the mountain region traversed by the Air Line railway. About 2½ miles from the town of Toccoa the creek of that name falls 155 feet over a precipice. Fifteen miles beyond Toccoa are the cascades of Tallulah, where the river descends successive terraces of broken rock between the walls of a chasm 800 feet deep. In this vicinity are the charming valley of Nacoochee and Mount Yonah. In the extreme north-east is Rabun gap and the cascades of Eastatoia. Connected with this region, once the hunting-grounds of the warlike Cherokees, are many Indian legends. The country between Atlanta and Chattanooga is deeply interesting from having been the battle-ground of opposing armies in the civil war. Kenesaw mountain, itself the scene of a bloody encounter, commands a view of the country which for two months the Confederate commanders disputed

foot by foot. Stone mountain, 9 miles from Decatur, is much visited. The Chattahoochee, in the neighbourhood of Columbus, is picturesque; and Savannah is one of the most attractive and idiosyncratic cities of the Union. There are numerous mineral springs scattered over the State, which are much resorted to by invalids.

History.—Before the arrival of Europeans the country now embraced in Georgia was inhabited by the Cherokee and Creek Indians. The Cherokees possessed the north, the Creeks the south. Both were very powerful and warlike, the Cherokees numbering 6000 warriors, and having 64 towns and villages. To be more precise, the Cherokee country extended from the 34th parallel north to the country of the Six Nations, and from the heads of the rivers emptying upon the South Carolina coast westward to the Mississippi. The whole course of the Tennessee was within this magnificent domain, now mostly embraced in the four States of Georgia, Alabama, Mississippi, and Tennessee. In 1739 this extensive territory was surrendered by treaty to the crown of Great Britain. The following year the Cherokees made formal submission to Sir A. Cumming, Bart.

Georgia was the only one of the original thirteen colonies that received any aid in its settlement from the Government of England. General James Oglethorpe conceived and executed the plan of founding an English colony in that portion of the Carolina proprietaries' grant between the Savannah and Altamaha. His purpose was to create an asylum in the New World where insolvent debtors, and persons fleeing from religious persecution, might begin life anew or enjoy religious freedom. By royal letters-patent issued in June 1732 the proposed colony was called Georgia in honour of the reigning prince; and the House of Commons granted £10,000, which was soon increased by private subscription to £36,000. Under the charter the trustees had powers of legislation, but could receive no reward for their services. Even grants of land to themselves were forbidden.

With 116 emigrants Oglethorpe sailed from England in November 1732, arriving in the Savannah in February. He landed at the present site of Savannah, where he was soon after hospitably received by delegates from the Lower Creeks, who consented that the English might peaceably inhabit among them. The next year a small number of Bavarians came over, and were settled in what is now Effingham county. Oglethorpe also established settlements at Darien, at Augusta, and on St Simon's island. In 1736 the colony received considerable accessions of emigrants, with whom came John and Charles Wesley, the founders of Methodism. In 1738 the Rev. George Whitefield visited Georgia, founding the orphan-house at Bethesda, near Savannah, from funds chiefly collected on his tour in the northern colonies.

Anticipating invasion by the Spaniards of Florida, who claimed Georgia, Oglethorpe, on the renewal of war between England and Spain, led an expedition to St Augustine, Florida, which he besieged without success at the head of 2000 men. The Spaniards retailed by landing in 1742 a small force on St Simon's island, from which they were expelled by Oglethorpe. They then abandoned further attempts. Slavery was introduced into Georgia about 1750. In 1752 the trustees surrendered their privileges to the crown. A royal governor and council were appointed to administer, in conjunction with delegates of the people, the government of the province. During the French and Indian wars the remote settlements suffered somewhat from incursions of the Cherokees. The treaties of 1763 with France and Spain extended the boundaries of Georgia to the Mississippi on the W., and to St Mary's on the S. After this the colony flourished greatly until the breaking

out of war with England, at which time the colony was estimated to have a population of about 70,000 souls. In 1775 Sir James Wright, the crown governor, left the province. Delegates were sent to represent Georgia in the continental congress who signed the Declaration of Independence. In 1778 a British land and naval force occupied Savannah and Augusta, but were subsequently compelled to abandon the latter place. In September of the same year a combined American and French force, under Lincoln and D'Estate, unsuccessfully attempted the recovery of Savannah, losing nearly 1000 men in an assault. Augusta was recaptured by the conquerors. Charleston being surrendered by General Lincoln in 1780, the patriots of South Carolina and Georgia were only able to maintain a partisan warfare, until the advance of General Greene from the north, at the head of considerable forces, resulted in the expulsion of the royal troops from those provinces. Georgia at the conclusion of peace ratified the several Acts constituting her one of the United States of America. She framed her first constitution in 1777, a second in 1789, and a third (which has been several times amended) in 1798.

In 1803 Georgia ceded to the general government all her territory west of the Chattahoochee, amounting to nearly 100,000 square miles, out of which the States of Alabama and Mississippi were subsequently formed. The cession of Louisiana to the United States was of great benefit to Georgia in ending hostilities which the Spaniards were continually inciting the Indians to commit upon the scattered settlements. By a treaty with the Creeks, Georgia became possessed of a large tract in the south-west of the State. The second war with England (1812-15) involved Georgia in hostilities with the Indians on her western border, who were finally subdued by General Andrew Jackson. In 1821 the cession of Florida to the United States relieved Georgia from the long series of Spanish aggressions beginning with her existence as a colony.

In 1825 a serious difficulty arose between the State and national authorities in consequence of proceedings by the Georgia executive to extinguish the title to lands in the State held by the Creeks and Cherokees. The head chief of the Creeks, McIntosh, was assassinated by his people for signing away these lands to the whites. By an Act of Congress passed in 1830, these Indians were subsequently removed to the Indian territory west of the Mississippi.

Georgia formally seceded from the Union in January 1861. The Government forts and arsenals were seized. The first military operations were on the coast. In April 1863 Fort Pulaski, one of the defences of Savannah, was recaptured by the Federal forces under Com. Du Pont. St. Mary's, Brunswick, Darien, and St. Simon's island were also occupied.

In the beginning of 1863 the Federal forces were in possession of middle and west Tennessee. In September they occupied Chattanooga in strong force, the Confederates falling back by the Western and Atlantic Railway to Lafayette, Ga. A further advance by General Rosecrans, the Federal commander, brought on the severely contested battle of Chickamauga, on the creek of that name (September 20). The Federals retreated to Chattanooga, which was soon threatened by the Confederates under Bragg. In November the Union army under General Grant drove Bragg from all his positions. In the spring of 1864 the southern army was at Dalton, Ga., on the railway to Atlanta, which it covered. In May General Sherman moved forward against this force a numerous and well-appointed Union army. Severe battles took place at Resaca, Kingston, and Allatoona Pass. A series of strategic movements, signalled by frequent bloody conflicts between the rival armies, resulted in the possession of Atlanta by the Union forces, September 2. From this point Sherman began in Nov-

ember his memorable march across Georgia to the sea. On December 10th he arrived in the neighbourhood of Savannah, captured Fort McAllister by assault, and occupied the city on the 21st. A cavalry force under General Wilson entered Georgia from Alabama in April 1865, capturing Columbus, West Point, and Macon, and making Davis, the Confederate States president, prisoner. In June 1865 a provisional governor was appointed for the State by the president of the United States. A convention assembled in October at Milledgeville, which repealed the ordinance of secession, abolished slavery, and declared the war debt void. A new constitution was framed and ratified in 1868, and Rufus B. Bullock inaugurated as governor. The restoration of civil government under the new forms was not effected in Georgia without complications which retarded its re-establishment on a solid foundation, but the amendments to the national constitution were at length adopted, and her senators and representatives were admitted to seats in Congress in December 1870. During the war Georgia furnished about 80,000 soldiers for the Confederate armies. She emerged from it with her industries prostrated, her treasury empty, her social and political system revolutionized, her most flourishing cities in ruins. Her great natural resources are fast advancing her to a commanding position among her sister States; and these resources are developing in the hands of a free people with greater rapidity and advantage than when half the population was enslaved. Texas possibly excepted, no southern State has a greater future than Georgia.

GEORGSWALDE, a town of Northern Bohemia, on the borders of Saxony, in the circle of Leitmeritz, about 35 miles E. of Dresden, with a station on the North Bohemian railway. Besides Old and New Georgswalde, it comprises Wiesenau and Philippsdorf, the latter a place which since 1868 has attained celebrity through the miracles attributed to its image of the Virgin. Georgswalde was founded in the beginning of the 17th century, and ranks as one of the oldest industrial centres of Bohemia, sharing with the neighbouring town of Rumburg a reputation for excellent linen. The parish church is a fine building. In 1869 the total population was 8230, of whom 5671 were in Old Georgswalde.

GERA, the chief town of the principality of Reuss-Schleiz, stands in a valley on the banks of the White Elster, 35 miles S.S.W. of Leipzig. It has been all rebuilt since a great fire in 1780, and the streets are in general wide and straight, and contain many handsome houses. The principal buildings are the churches of St. Salvator's and St. Trinity, the town-hall, the buildings of the imperial bank and of the Gera bank, the music hall, and the central hall. Its educational establishments include a gymnasium, a general town school (which contains a real school of the first order, a higher female school, and three citizen schools), a commercial school, a normal school, and a weaving school. The castle of Osterstein, the residence of the prince of Reuss, dates from the 9th century, but has been nearly all rebuilt within the last thirty years. Gera has long been noted for its industrial activity. Its manufactures comprise woollen, cotton, and silk goods, tapestry, artificial flowers, oil-cloth, leather, hats, tobacco, soap, beer, vinegar, chocolate, glue, porcelain and other earthenware, bricks, musical instruments, and carriages.

Gera was raised to the rank of a town in the 11th century, at which time it belonged to the counts of Groitzsch. In the 12th century it came into the possession of the lords of Reuss. It was stormed and sacked by the Bohemians in 1450, was two-thirds burned down by the Swedes in 1639 during the Thirty Years' War, and suffered afterwards from great conflagrations in 1686 and 1780, being in the latter year almost completely destroyed. The population in 1875 was 20,810, nearly all of whom are Protestants.

GERACE or GERACI, a town of Italy in the province of Reggio di Calabria, about 59 miles from Reggio on the railway between that city and Monasterace, is situated on a limestone hill not far from the coast, 30 miles N.N.E. of Cape Spartavento, between the rivers Merico and Novito. It is the seat of a bishop and of a subprefect, and has a civil and criminal court dependent on that of Catanzaro. The citadel, formerly of great strength, was reduced to ruins by the earthquake of 1793, and the cathedral was at the same time so severely injured that only a portion of the crypt remained available for public worship. There is a good trade in a white wine known as *Vino Greco*, silk is manufactured; and the warm sulphur springs of the neighbourhood attract patients to the town. About 5 miles off, at Torre di Gerace, are the ruins of the Greek city of Locri Epizephyni, from which Gerace derived materials for its buildings, and more especially fine marble columns for the cathedral. The population in 1871 was 7257. This Gerace is not to be confounded with Gerace Siculo, a town of between 8000 and 4000 inhabitants, 4 miles from Cefalù, which was the first place in Sicily erected into a marquisate.

GERANIUM is the name of a genus of polypetalous exogenous plants, which is taken by botanists as the type of the natural order *Geraniaceae*. The name, as a scientific appellation, has a much more restricted application than when taken in its popular sense. Formerly the genus *Geranium* was almost continuous with the order *Geraniaceae*, which latter had then a more limited meaning than is given to it by those of our leading botanists of the present day who include in it the *Tropaeolaceae*, the *Oxalidaceae*, and the *Balsaminaceae*. Then as now the geranium was very popular as a garden plant, and the species included in the original genus became widely known under that name, which has more or less clung to them ever since, in spite of scientific changes which have removed the larger number of them to the genus *Pelargonium*. This result has been probably brought about in some degree by an error of the nurserymen, who seem in many cases to have acted on the conclusion that the group commonly known as *Scarlet Geraniums* were really geraniums and not pelargoniums, and have in consequence inserted them under the former name in their trade catalogues. In fact it may be said that, from a popular point of view, the pelargoniums of the botanist are better known as geraniums than are the geraniums themselves.

The species of *Geranium* bear the English name of Cranesbill, and consist mostly of herbs, of annual or perennial duration, dispersed throughout the temperate regions of the world. They number nearly a hundred, and bear a considerable family resemblance. The leaves are for the most part palmately-lobed, and the flowers are regular, consisting of five sepals, five imbricating petals, alternating with five glandules at their base, ten stamens, and a beaked ovary. Some dozen or more species are natives of the British Isles, and many of those of exotic origin form handsome border plants in our gardens of hardy perennials. Amongst these *G. viviparum*, *G. platyptalum*, *G. sanguineum*, *G. Bucktonianum*, and the double-flowered varieties of *G. pratense* are conspicuous. The genus is not without its virtues, *G. maculatum* being the alum-root of North America, used there as an astringent in diarrhoea, dysentery, and such like complaints, while the native Herb Robert of English hedgesides, *G. Robertianum*, which is both astringent and aromatic, is used as a remedy in nephritic disorders.

From these regular-flowered herbs, with which they had been mixed up by the earlier botanists, L'Heritier in 1787 separated those plants which have since borne the name of *Pelargonium*, and which, though agreeing with them in certain points of structure, differ in others which are admitted to be of generic value. One obvious distinction of

Pelargonium is that the flowers are irregular, the two petals which stand uppermost being different—larger, smaller, or differently marked—from the other three, which latter are occasionally wanting. This difference of irregularity the modern florist has done very much to annul, for the increased size given to the flowers by high breeding has usually been accompanied by the enlargement of the smaller petals, so that a very near approach to regularity has been in some cases attained. Another well-marked difference however remains in *Pelargonium*, the back or dorsal sepal is furnished with a hollow spur, which spur is adnate, *i.e.* joined for its whole length with the flower-stalk; while in *Geranium* there is no spur. This peculiarity is best seen by cutting clean through the flower-stalk just behind the flower, when in *Pelargonium* there will be seen the hollow tube of the spur, which in the case of *Geranium* will not be found as it does not exist, but the stalk will appear as a solid mass. There are other characters which support those already pointed out, such as the absence of the glandules, and the declination of the stamens; but the features already described offer the most ready and obvious distinctions.

To recapitulate, the geraniums properly so-called are regular flowered herbs with the flower stalks solid, while many geraniums falsely so-called in popular language are really pelargoniums, and may be distinguished by their irregular flowers and hollow flower stalks. In a great majority of cases too, the pelargoniums so commonly met with in greenhouses and summer parterres are of shrubby or sub-shrubby habit.

GERARD of CREMONA (1114–1187), the mediæval translator of Ptolemy and Avicenna, was born at Cremona, Lombardy, in 1114. Dissatisfied with the meagre philosophies of his Italian teachers, he went to Toledo to study among the Moors, who were at that time the chief depositaries and interpreters of the wisdom of the ancients; and, having thus acquired a knowledge of the Arabic language, he appears to have devoted the remainder of his life to the business of making Latin translations from its literature. The date of his return to his native town is uncertain, but he is known to have died there in 1187. His original version of Avicenna's *Canon of Medicine* was the basis of all the very numerous subsequent Latin editions of that well-known work; and the Latin translation by which alone Ptolemy's *Almagest* until the discovery of the original *μεγάλη σύνταξις* was known to Europe is also ascribed to him. In addition to these, he translated various other treatises in medicine, mathematics, and astronomy, to the number, it is said, of sixty-six; but some of the works with which he has been credited (including the translation of the *Almansor* of Er-Razi or Rhazes) are more probably due to a later Gerard also called "Cremouensis," but more precisely "de Sabloneta." See Boncompagni, *Della Vita e delle Opere di Gherardo Cremonense e di Gherardo da Sabbioneta*.

GERARD, variously surnamed TUM, TUNC, TENQUE, or THOM (c. 1040–1120), founder of the order of the knights hospitalers of St John or of Malta, was born at Amalfi about the year 1040. According to other accounts Martigues in Provence was his birthplace, while one authority even names the Château d'Avesnes in Hainaut. Whether as a soldier or a merchant, he in the course of the latter part of the 11th century found his way to Jerusalem, where a hospice had for some time existed for the convenience of those who wished to visit the holy places. Of this institution Gerard became guardian or provost at a date not later than 1100; and here he organized that religious order of St John which received papal recognition from Pascal II. in 1113, by a bull which was renewed and confirmed by Calixtus II. shortly before the death of Gerard in 1120.

GÉRARD, ÉTIENNE MAURICE, COUNT (1773-1852), a distinguished French general, was born at Damvilliers in the department of Meuse, 4th April 1773. He joined the second battalion of the Meuse in 1791, and served in the campaigns of 1792-1793 under Generals Dumouriez and Jourdan. In 1798 he accompanied Bernadotte as aide-de-camp in his embassy to Vienna. In 1799 he was named chief of a squadron, and in 1800 colonel. He distinguished himself by a brilliant charge against the Russian imperial guard at the battle of Austerlitz, and being raised to the rank of general in November 1806, played a prominent part in the battles of Halle, Jena, and Erfurt; and for his conduct in the battle of Wagram, where he greatly contributed to the victory, he was created a baron. In the Spanish campaign of 1810 and 1811 he gained special distinction at the battle of Fuentes-de-Onoro; and in the subsequent expedition to Russia he was present at the capture of Smolensk, had a principal share in the victory of Walontna-Gora, displayed such bravery and ability in the battle of the Moskova that he was made general of division, and by his coolness and energy in the disastrous retreat from Moscow saved the rearguard of the French army at the passage of the Wilna. In the campaign of 1813, in command of a division under Macdonald, he took part in the battles of Lutzen, Bautzen, Goldberg, and Leipsic, where he was dangerously wounded. After the battle of Bautzen he was created by Napoleon a count of the empire. In the campaign of France of 1814, in command of the army of reserves composed chiefly of recruits, he by his skilful manoeuvres powerfully assisted in securing the victories of Nogent, Nangis, and Montreuil-sur-Yonne. After the first restoration he was named by Louis XVIII. grand cross of the legion of honour and chevalier of St Louis. On the return of Napoleon from Elba he was entrusted with the command of the army of the Moselle, and took part in the battle of Lugny. On the morning of the battle of Waterloo, being under the orders of Grouchy, who was marching towards Wavre, he strongly urged him to proceed in the direction whence they heard cannon firing, but his advice was not followed. Gérard retired to Brussels after the fall of Napoleon, and did not return to France till 1817. He was chosen a member of the chamber of deputies in 1822, and was re-elected in 1823 and 1827. He took part in the revolution of 1830, after which he was appointed minister of war and named a marshal of France. On account of his health he resigned the office of war minister in the October following, but in 1831 he took the command of the northern army, and was successful in thirteen days in driving the army of Holland out of Belgium. In 1832 he compelled the surrender of Antwerp, and in the same year he was raised to the peerage of France. He was again chosen war minister in July 1834, and again resigned that office in the October following. In 1835 he was named grand chancellor of the legion of honour, and in 1838 commander-general of the national guards of the Seine, an office which he held till 1842. He became a senator under the empire in 1852, and died in April of the same year.

GÉRARD, FRANÇOIS, BARON (1770-1837), was born on May 4, 1770, at Rome, where his father occupied a post in the house of the French ambassador. At the age of twelve Gérard left Rome with his family for Paris, and there obtained admission into the Pension du Roi. From the Pension he passed to the studio of Pajou (sculptor), which he left at the end of two years for that of the painter Brenet, whom he quitted almost immediately to place himself under David. In 1789 Gérard competed for the Prix de Rome, which was carried off by his comrade Girodet. In the following year (1790) he again presented himself, but the death of his father prevented the completion of his work, and obliged him to accompany his mother to Rome.

In 1791 he returned to Paris; but his poverty was so great that he was forced to forego his studies in favour of employment which should bring in immediate profit. David at once availed himself of his help, and one of that master's most celebrated portraits—Le Pelletier de St Paignon—is due to the hand of "le petit Gérard." This portrait was executed early in 1793, the year in which Gérard, at the request of David, was named a member of the revolutionary tribunal, from the fatal decisions of which he, however, invariably absented himself. In 1794 he obtained the first prize in a competition, the subject of which was "The Tenth of August," and, further stimulated by the successes of his rival and friend Girodet in the Salons of 1793 and 1794, Gérard (nobly aided by Isabeau the miniaturist) produced in 1795 his famous "Bélisaire." In 1796 a portrait of his generous friend (Louvre) obtained undisputed success, and the money received from Isabeau for these two works enabled Gérard to execute in 1797 his "Psyché et l'Amour." At last, in 1799, his portrait of Madame Bonaparte established his position as one of the first portrait painters of the day. In 1808 as many as eight, in 1810 no less than fourteen portraits by him, were exhibited at the Salon, and these figures afford only an indication of the enormous numbers which he executed yearly; all the leading figures of the empire and of the restoration, all the most celebrated men and women of Europe, sat to Gérard. This extraordinary vogue was due partly to the charm of his manner and conversation, for his *salon* was as much frequented as his studio; Madame de Staël, Canning, Talleyrand, the duke of Wellington, have all borne witness to the attraction of his society. Rich and famous, Gérard was stung by remorse for earlier ambitions abandoned, at intervals he had indeed striven to prove his strength with Girodet and other rivals, and his "Bataille d'Austerlitz" (1810) showed a breadth of invention and style which are even more conspicuous in "L'Entrée d'Henri IV." (Versailles),—the work with which in 1817 he did homage to the Bourbons. After this date Gérard declined, watching with impatient grief the progress of the Romantic school. Loaded with honours—baron of the empire, member of the Institute, officer of the legion of honour, first painter to the king—he worked on sad and discouraged, the revolution of 1830 added to his disquiet; and in 1837 on 11th January, after three days of fever, he died. By his portraits Gérard is best remembered; the colour of his paintings has suffered, but his drawings show in unimpaired delicacy the purity of his line; and those of women are specially remarkable for a virginal simplicity and frankness of expression.

M. Ch. Lenormant published in 1846 *Essai de Biographie et de Critique sur François Gérard*, a second edition of which appeared in 1847, and M. Delteil devoted several pages to the same subject in his work *Louis David, son école et son temps*.

GÉRARD, JEAN IGNACE ISIDORE (1803-1847), a French caricaturist generally known by the pseudonym of Grandville—the professional name of his grandparents, who were actors—was born at Nancy, 13th September 1803. He received his first instruction in drawing from his father, a miniature painter, and at the age of twenty-one came to Paris, where he soon afterwards published a collection of lithographs entitled *Les tribulations de la petite propriété*. He followed this by *Les plaisirs de tout âge*, and *La sylvie des salons*; but the work which first established his fame was *Métamorphoses du jour*, published in 1828, a series of 70 scenes in which individuals with the bodies of men and faces of animals are made to play a human comedy. These drawings are remarkable for the extraordinary skill with which human characteristics are represented in animal features, but they are liable to the objection of attempting to express by the pencil what can be properly done only by the pen; while at the same time, in conquering difficulties

incident to his purpose, much ingenuity and labour has been wasted which might have been employed otherwise with better results. The success of this work led to his being engaged as artistic contributor to various periodicals such as *La Silhouette*, *L'Artiste*, *La Caricature*, *Le Charivari*, and his political caricatures, which were characterized by marvellous fertility of satirical humour, soon came to enjoy a general popularity which never diminished. Besides supplying illustrations for various standard works, such as the songs of Béranger, the fables of La Fontaine, *Don Quixote*, *Gulliver's Travels*, *Robinson Crusoe*, he also continued the issue of various lithographic collections, among which may be mentioned *La vie privée et publique des animaux*, *Les cent proverbes*, *L'autre monde*, and *Les fleurs animées*. Though the designs of Gérard are occasionally unnatural and absurd, they usually display keen analysis of character and marvellous inventive ingenuity, and his humour is always tempered and refined by delicacy of sentiment and a vein of sober thoughtfulness. He died of mental disease 17th March 1847.

A short notice of Gérard, under the name of Grandville, is contained in Theophile Gautier's *Portraits Contemporains*. See also Charles Blanc, *Grandville*, Paris, 1855.

GERARD, JOHN (1545–1608), herbalist and surgeon, was born towards the end of 1545 at Nantwich in Cheshire. He was educated at Wisterton, or Willaston, 2 miles from Nantwich, and eventually, after spending some time in travelling, took up his abode in London, where he exercised his profession. For more than twenty years he also acted as superintendent of the gardens of Lord Burghley, secretary of state to Queen Elizabeth. In 1596 he published a catalogue of plants cultivated in his own garden, 1039 in number, inclusive of varieties of the same species. Their English as well as their Latin names are given in a revised edition of this catalogue issued in 1599. In 1597 appeared Gerard's well-known *Herball*, described by him in its preface as "the first fruits of these mine own labours," but more truly an adaptation of the *Stirpium historia pemptales* of Rembert Dodoens, published in 1583, or rather of a translation of the whole or part of the same by Dr Priest, with L'Obel's arrangement. Of the numerous illustrations of the *Herball* sixteen appear to be original, the remainder are mostly impressions from the wood blocks employed by Jacob Theodorus (Tabernaemontanus) in his *Icones Stirpium*, published at Frankfort in 1590. A second edition of the *Herball*, with considerable improvements and additions, was brought out by Thomas Johnson in 1633, and reprinted in 1636. Gerard was elected a member of the court of assistants of the barber-surgeons in 1595, by which company he was appointed an examiner in 1598, junior warden in 1605, and master in 1608. He died in February 1612, and was buried at St Andrews, Holborn.

See Johnson's preface to his edition of the *Herball*; and *A Catalogue of Plants cultivated in the Garden of John Gerard in the years 1596–1599*, edited with Notes, References to Gerard's *Herball*, the *Addition of modern Names*, and a *Life of the Author*, by Benjamin Dwyden Jackson, F.L.S., privately printed, Lond., 1876, 4to.

GERARD DE NERVAL (1808–1855) is the adopted name of Gérard Labrunie, a French littérateur, and that by which he is generally known. The son of an officer in the army, and born at Paris, May 21, 1808, he received his early education chiefly from his father, who taught him German, and he afterwards studied at the college of Charlemagne. He made his literary début by the publication of a volume of political odes, and in 1828 he published a translation of Goethe's *Faust*, of which Goethe himself expressed high approval, and the choruses of which were afterwards made use of by Berlioz for his legend-symphony, *The Damnation of Faust*. Several other translations from the German, contributed chiefly to the *Mercur de France*, a number of poetical pieces, and three comedies

combined to acquire for him, at the age of twenty-one, a considerable literary reputation, and led to his being associated with Theophile Gautier in the preparation of the dramatic *feuilleton* for the *Presse*. On the death of Jennie Colon, an actress with whom he had contracted a *liaison*, he resigned his connexion with the *Presse*, and travelled in various parts of Europe, leading a somewhat dissipated life. He contributed an account of his travels to the *Revue des Deux Mondes* and other periodicals. After his return to Paris in 1844 he resumed for a short time the *feuilleton*. From 1841 he was subject to periodical attacks of insanity, and he committed suicide by hanging, 25th January 1855. The literary style of Gérard is simple and unaffected, and he has a peculiar faculty of giving to his imaginative creations an air of naturalness and reality. In a series of novellettes, afterwards published under the name of *Les Illuminés ou les Précurseurs du Socialisme* (1852), he gave a sort of analysis of the feelings which followed his third attack of insanity, and among his numerous other works the principal are *Élégies nationales et Satires politiques*, 1827; *Scènes de la Vie Orientale*, 2 vols., 1848–1850; *Contes et Fables*, 1852; *La Bohème galante*, 1856, and *L'Alchimiste*, a drama in five acts, the joint composition of Gérard and Alexander Dumas. His *Œuvres complètes* were published in 1868 in 5 volumes.

GERASA, the modern GERASH or JERASH, a city of Palestine, in the Decapolis of Perea, situated amid the mountains of Gilead, about 1757 feet above the level of the sea, at a distance of 20 miles from the Jordan and 21 miles to the north of Philadelphia. Of its origin nothing is known. Its name is never mentioned in the Old Testament, and in the New Testament the only reference to its existence is the alternative reading of Geraseses for Gadarenes in Matthew viii. 28. From Josephus we learn that it was captured by Alexander Jannæus, burned by the Jews in revenge for the massacre at Casarea, and again plundered and depopulated by Annian the general of Vespasian; but in spite of these disasters it was still in the 2d and 3d centuries of the Christian era one of the wealthiest and most flourishing cities of Palestine. As late as 1121 it gave employment to the soldiers of Baldwin II., who found it defended by a castle built by a king of Damascus; but at the beginning of the following century the Arabian geographer Yakut speaks of it as deserted and overthrown. The ruins of Jerash, discovered by Seitzon about 1806 and since then frequently visited and described, still attest the splendour of the Roman city. They are distributed along both banks of the Kerwan, a brook which flows south through the Wady-ed-Dér to join the Zerka or Jabbok; but all the principal buildings are situated on the level ground to the right of the stream. The town walls, which can still be traced and indeed are partly standing, had a circuit of not more than 2 miles, and the main street was less than half a mile in length, but remains of buildings skirt the road for fully a mile beyond the south gate, and show that the town had far outgrown the limit of its fortifications. The most striking feature of the ruins is the profusion of columns, no fewer than 250 being even now in position: the main street is a continuous colonnade, a large part of which is still entire, and it terminates to the south in a forum of similar formation. Among the public buildings still recognizable are a theatre capable of accommodating 6000 spectators, a naumachia or circus for naval combats, and several temples, of which the largest was probably the grandest structure in the city, possessing a portico of Corinthian pillars 38 feet high. The desolation of the city is probably due to earthquake; and the absence of Moslem erections or restorations would seem to show that the disaster took place before the Mahometan period.

GERBA or JERBA, German *Decherba*, an island off the African coast in the Gulf of Gabes, belonging to the regency of Tunis. It is flat and well wooded with date palms, has an area of 425 square miles, and contains a population of 30,000. Most of the inhabitants are of Berber origin, though a certain proportion have adopted the Arabic language. About 5000 Jews live apart in villages of their own, and a number of European merchants are settled in the chief town of Hautes-Suk for the purposes of trade. The island has a considerable reputation for the manufacture of the woollen tissues interwoven with silk which are known as burnous stuffs; a market for the sale of sponges from the neighbouring seas is held from November till March; and a good trade is maintained in the export of dates and other fruits. Gerba is the *Lophophagus* or *Lotus*-eaters' Island of the Greek and Roman geographers, and it may also be identified with the *Brachion* of Scylax. The modern name appears as early as the 3d century in Aurelius Victor, who, mentioning the births of the emperors Gallus Trebonianus and Volusianus his son, says—"Creati in insula Meninge, quæ nunc Cirba dicitur." *Meninge* or *Meninx* was the name of one of the two ancient towns in the island, the other being *Thoor*. A castle erected by the Spaniards in 1284 at Hautes-Suk still remains; but the pyramid built of the skulls of the Spaniards under Garcia, who perished in 1516, was removed in 1837.

See Barth, *Wanderungen durch die Küsten des Mittelmeeres*; and Maltzan, *Reise in Tunis und Tripolis*, Leipzig, 1870.

GERBER, ERNST LUDWIG (1746-1819), author of the well-known dictionary of musicians, was born at Sondershausen 29th September 1746. His father, Henry Nicolas Gerber (1702-1775), a pupil of J. S. Bach, was an organist and composer of some distinction, and under his direction Ernst Ludwig at an early age had made great progress in his musical studies. In 1765 he went to Leipzig with the view of studying law, but the claims of music, which had gained additional strength from his acquaintance with J. A. Hiller, soon came to occupy almost his sole attention. On his return to Sondershausen he was appointed music teacher to the children of the prince, and in 1775 he succeeded his father as court organist. Latterly he devoted much of his time to the study of the literature and history of music, and with this view he made himself master of several of the modern languages. His *Historisch-biographisches Lexicon der Tonkünstler* appeared in 1790 and 1793 in two volumes; and the first volume of what was virtually an improved and corrected edition of this work was published in 1810 under the title *Neues historisch-biographisches Lexicon der Tonkünstler*, followed by other three volumes in 1812, 1813, and 1814. Gerber also contributed a number of papers to musical periodicals, and published several minor musical compositions. He died at Sondershausen 30th June 1819.

GERBERON, GABRIEL (1628-1711), a Jansenist monk, one of the most diligent students and prolific writers of his century, was born August 12, 1628, at St Calais, in the department of Sarthe. At the age of twenty he took the vows of the Benedictine order at St Malo, Rennes, and after having taught rhetoric and philosophy in the monasteries of Bourgneil (Touraine) and St Denis, he became sub-prior at Compiègne, whence he was afterwards removed to St Germain-des-Près. In the year 1669 he fully and finally committed himself in the Jansenist controversy by the publication of his first work, which was an apology for the abbé Rupert of Tuits. In 1672 he was ordered to Argenteuil and in 1675 to Corbie; but having by this time aroused the most bitter hostility of the entire Jesuit order, he found it necessary to save himself by flight into the Low Countries, where he seems to have lived in various towns during the next twenty-eight years, and where

he published a great number of works, including the *Histoire Générale du Jansenisme* (1700), by which he is now best known. Arrested on the 30th of May 1703 at Brussels, at the instance of the archbishop of Malines, he was sent into France and condemned to imprisonment, from which he was not released till 1710, and even then only after he had consented to abjure the five Jansenist propositions. The first use he made of his freedom was to write a work (which, however, his friends prudently prevented him from publishing) *Le vaine trompe des Jésuites*, containing a virtual withdrawal of the compulsory recantation. He died at the abbey of St Denis on the 29th of March 1711. A full list of his works is given in the *Biographie Générale*.

GERBERT. See SILVESTER II.

GERBERT, MARTIN (1720-1793), a Catholic prelate and writer on church music, was a descendant of the Gerberts of Hornau, and was born at Horb on the Neckar, Württemberg, 12th August 1720. He received his education at the Jewish school of Freiburg in the Breisgau, at Klingental in Switzerland, and at the monastery of St Blaise in the Black Forest. He joined the order of the Benedictines in the monastery of St Blaise in 1736, became priest in 1744, was soon thereafter appointed professor of theology, and was chosen abbot in 1764. From 1759 to 1762 he travelled in Germany, Italy, and France, chiefly with the view of obtaining access to the old collections of musical literature contained in the libraries of the monasteries. In 1774 he published two volumes *De cantu et musica sacra*; in 1777, *Monumenta veteris liturgie Alemannica*; and in 1784, in three volumes, *Scriptores ecclesiastici de musica sacra*, a collection of the principal writers on church music from the 3d century till the invention of printing. Although this work contains many textual errors, its publication has nevertheless been of very great importance for the history of music, by preserving writings which otherwise might either have perished or remained unknown. He is also the author of *Codex epistolaris Rudolphi I.*, 1772, and *Historia Nigrae Sive*, Cologne, 1783-1788. His interest in music led to his acquaintance with the composer Gluck, who became his intimate friend. He died 3d May 1793.

GERHARD, FRIEDRICH WILHELM EDUARD (1795-1867), a distinguished German archaeologist, was born at Posen, 29th November 1795. After studying at Breslau and Berlin, he in 1816 took up his residence at the former town. The reputation he acquired by his *Lectiones Apolloniæ*, published in the same year, led soon afterwards to his being appointed professor at the gymnasium of Posen. On resigning that office in 1819, on account of weakness in the eyes, he travelled in Italy, and in 1822 he took up his residence in Rome, where, with the view of prosecuting his archaeological studies, he remained for fifteen years. He there contributed to Plücker's *Beschreibung der Stadt Rom*, then under the direction of Bunsen, and he was also one of the principal originators of the *Istituto di corrispondenza archeologica*, founded at Rome in 1828, and during his stay in Italy its director. After his return to Germany in 1837, he was appointed archaeologist at the Royal Museum of Berlin, and in 1844 he was chosen a member of the Academy of Sciences, and a professor in the university. He died at Berlin 12th May 1867.

Besides a large number of archaeological papers in periodicals, in the *Annali* of the Institute of Rome, and in the *Transactions* of the Berlin Academy, and several illustrated catalogues of Greek, Roman, and other antiquities in the Berlin, Naples, and Vienna Museums, Gerhard is the author of the following works:—*Antike Bildwerke*, Stuttgart, 1837-44. *Auslesene griech. Vasenbilder*, 1839-68; *Etruskische Spiegel*, 1839-65; *Hyperboreisch-rom. Studien*, vol. i., 1833; vol. ii., 1862. *Prodomus mytholog. Kunsterklärung*, Stuttgart and Tübingen, 1828; and *Griech. Mythologie*, 1854-65. His *Gesammelte akademische Abhandlungen und kleine Schriften* were published posthumously in 2 vols., Berlin, 1867.

GERHARD, JOHANN (1582–1637), one of the ablest and most learned exponents of Lutheran orthodoxy, was born of a good middle-class family in Quedlinburg, 17th October 1582. In his fifteenth year, during a dangerous illness, he came under the personal influence of Johann Arndt, author of *Das Wahre Christenthum*, and resolved to study for the church. Soon after entering the university of Wittenberg, however, in 1599, he began to waver in this determination, and ultimately gave himself for two years to the study of medicine, but in 1603 resumed his theological reading at Jena, and in the following year received a new impulse from Winkelman and Mentzer at Marburg. Having graduated and begun to give lectures at Jena in 1605, he in 1606 received and accepted the duke of Coburg's invitation to the superintendency of Heldburg and mastership of the gymnasium; soon afterwards he became general superintendent of the duchy, in which capacity he was much and usefully engaged in the practical work of ecclesiastical organization until 1616, when he found a more congenial sphere in the senior theological chair at Jena, where the remainder of his life was spent. Though still comparatively young, Gerhard had already come to be regarded as the greatest living theologian of Protestant Germany; in the numerous "disputations" which characterized that period he was always protagonist, while on all public and domestic questions touching on religion or morals his advice was eagerly sought on all hands and by every class. It is recorded that during the course of his lifetime he had received repeated calls to almost every university in Germany, as well as to Upsala in Sweden. He died on the 20th August 1637. Personally he is said to have exhibited a rare combination of all the best elements of the Christian character; the only failing imputed to him by any one decidedly leans to virtue's side—an excessive love of peace.

His writings are very numerous, alike in exegetical, polemical, dogmatic, and practical theology. To the first category belong the *Commentarius in harmoniam historice evangelice de passionis Christi* (1617), the *Conspectus super primum D. Petri Epistolam* (1641), and also his commentaries on Genesis (1637) and on Deuteronomy (1658). Of a controversial character are the *Confessio Catholica* (1684–88), an extensive work which seeks to prove the evangelical and catholic character of the doctrine of the Augsburg Confession from the writings of approved Roman Catholic authors; and the *Loca theologica* (1629), his principal contribution to science, in which Lutheranism is expounded "nervose, solide, et copiose," in fact with a fulness of learning, a force of logic, and a minuteness of detail that had never before been approached. The *Meditationes sacre* (1621), a work expressly devoted to the uses of Christian education, has been frequently reprinted in Latin and has been translated into most of the European languages, including Greek. The English translation by R. Winterton (1631) has passed through at least nineteen editions. There is also an edition by W. Papillon in English blank verse (1801). *A Vita Joh. Gerhardi* was published by E. R. Fischer in 1723.

GERHARDT, CHARLES FREDERIC, was born at Strassburg, August 21, 1816, and died there August 19, 1886. After his school years spent at home and in Carlsruhe, where his taste for chemistry was awakened, he was sent to Leipzig to learn business, but he attended Erdmann's lectures on chemistry as well. Returning home he very soon found that a commercial life was not to his taste, so, after a sharp dispute with a disappointed father, he enlisted in a cavalry regiment. In a few months a military career also became intolerable, and, being bought off by a friend, he went to Giessen to study under Liebig. There he remained eighteen months, displaying such entire devotion to chemistry that he found himself unable to obtain the customary degree. He again thought of entering trade, but Liebig persuaded him to go to Paris, where he arrived in 1838. His good appearance and address recommended him to Dumas and other chemists, and in a short time along with Cahours, who became his intimate friend, he published an important memoir on essential oils, distinguished especially by the new views it contained. He

soon after left Paris and went to Montpellier, where he was professor in the faculty of science till 1848. He then returned to Paris and opened a school for chemistry, which, however, was not commercially a success. From 1848 to 1855 he resided at Paris, and it was during this time that he published the memoirs and carried on the controversies which have been of such importance in the development of scientific chemistry. In 1855 he was appointed professor at Strassburg, his native place, but he had held the office for but a short time when he died, after two days' illness. Gerhard's contributions to chemistry are less discoveries of new facts, than of new ideas which organized and vitalized an inert accumulation of facts. He developed the notion of types of structure and reaction, he discovered the order of organic compounds, which led him to the doctrine of homologous and other series, and on theoretical grounds he remodelled the whole character of the combining weights upon the two-volume molecular basis. The bare statement, however, of his results gives no idea of the lucidity, the wealth of thought, the grasp of the entire subject which his memoirs and his longer works display. It was by his writings especially that Gerhard's influence was felt. Although a thorough enthusiast in his subject, clear in his exposition, earnest in his work, weighty in his delivery, he seems to have wanted the qualities of a successful teacher. Nothing is heard of his lectures, or of his influence as a professor,—such influence as drew students round Liebig and other great masters. None the less, however, did he stir the thoughts of other chemists to the very depths; and although the unitary system has had its day, yet, in substance at least, if no longer in name, chemistry is still Gerhard's, and it is not impossible that chemists may return to some of his views which at present are not acceptable.

GERHARDT, PAUL (c. 1606–1676), the greatest hymn-writer of Germany, if not indeed of Europe, was born of a good middle-class family at Gräfenhainichen, a small town on the railway between Halle and Wittenberg, in 1606 or 1607,—some authorities, indeed, give the date March 12, 1607, but neither the year nor the day is accurately known. His education appears to have been retarded by the troubles of the period, the Thirty Years' War having begun about the time he reached his twelfth year. After completing his studies for the church he is known to have lived for some years at Berlin as tutor in the family of an advocate named Berthold, whose daughter he subsequently married, on receiving his first ecclesiastical appointment at Mittelwald (a small town in the neighbourhood of Berlin) in 1651. In 1657 he accepted an invitation as "diaconus" to the Nicolai-kirche of Berlin; but, in consequence of his uncompromising Lutheranism in refusing to accept the elector Frederick William's "syncretistic" edict of 1664, he was deprived in 1666. Though absolved from submission and restored to office early in the following year, on the petition of the citizens, his conscience did not allow him to retain a post which, as it appeared to him, could only be held on condition of at least a tacit repudiation of the Formula Concordia, and for upwards of a year he lived in Berlin without fixed employment. In 1668 he was appointed archdeacon of Lubben in the duchy of Saxe-Merseburg, where, after a somewhat sombre ministry of eight years, he died on the 7th of June 1676. Many of his best known hymns were originally published in various church hymn-books, as for example in that for Brandenburg which appeared in 1658; others first saw the light in Johann Crüger's *Geistliche Kirchenmelodien* (1649) and *Praes Pietatis Melica* (1656). The first complete set of them is the *Geistliche Andachten*, published in 1666–67 by Ebeling, music director in Berlin. No hymn by Gerhardt of a later date than 1667 is known to exist.

The life of Géricault has been written by Roth (1829), by Langbecken (1841), by Schnitz (1842), by Wildenhahn (1845), and by Bachmann (1893); also by Kraft in Ersch u. Gruber's *Allg. Encycl.* (1855). The best modern edition of the hymns, published by Wackernagel in 1843, has often been reprinted. There is an English translation by Kelly (*Paul Gericault's Spiritual Songs*, 1867).

GÉRICAUT, JEAN LOUIS ANDRÉ ТИХОМОНЕ (1791–1824), French painter, led the inevitable reaction which set in under the empire against the fixed and strictly limited aims of the school of David. He was born at Rouen in 1791. In 1808 he entered the studio of Charles Vernet, from which, in 1810, he passed to that of Guérin, whom he dove to despair by his passion for Rubens, and by the unorthodox manner in which he persisted in interpreting nature. At the Salon of 1812 Géricault attracted attention by his “Officier de Chasseurs à Cheval” (Louvre), a work in which he personified the cavalry in its hour of triumph, and turned to account the solid training received from Guérin in rendering a picturesque point of view which was in itself a protest against the cherished convictions of the pseudo-classical school. Two years later (1814) he re-exhibited this work accompanied with the reverse picture “Cuirassier blessé” (Louvre), and in both subjects called attention to the interest of contemporary aspects of life, treated neglected types of living form, and exhibited that mastery of and delight in the horse which was a feature of his character. Disconcerted by the tempest of contradictory opinion which arose over these two pictures, Géricault gave way to his enthusiasm for horses and soldiers, and enrolled himself in the *mousquetaires*. During the Hundred Days he followed the king to Belgium, but, on his regiment being disbanded, eagerly returned to his profession, left France for Italy in 1816, and at Rome nobly illustrated his favourite animal by his great painting “Course des Chevaux Libres.” Returning to Paris, Géricault exhibited at the Salon of 1819 the “Radeau de la Méduse” (Louvre), a subject which not only enabled him to prove his zealous and scientific study of the human form, but contained those elements of the heroic and pathetic, as existing in situations of modern life, to which he had appealed in his earliest productions. Easily depressed or elated, Géricault took to heart the hostility which this work excited, and passed nearly two years in London, where the “Radeau” was exhibited with success, and where he executed many series of admirable lithographs now rare. At the close of 1822 he was again in Paris, and produced a great quantity of projects for vast compositions, models in wax, and a horse *écorché*, as preliminary to the production of an equestrian statue. His health was now completely undermined by various kinds of excess, and on 26th January 1824 he died at the age of thirty-three. That which he left us is effective only as a protest; his work, like his life, lacked the fixity of conscious purpose necessary to the task of reconstruction. Had he steadied himself and survived the abuse of his powers, he might have played an important part in determining the course of the modern school, for, though no colourist, he was in other respects richly endowed, and was possessed by a rare energy which redeemed even that tendency to undue emphasis which gives a theatrical character to much of the best French work. Géricault's biography, accompanied by a *catalogue raisonné* of his works, was published by M. C. Clément in 1868.

GERIZIM (גֵּרִיזִים, “the desert hill,” or, according to others, “the hill of the Gerizites”), the third highest mountain of Samaria,² is situated at the western extremity

of the fertile plain of Mochna, and with Mount Ebal, which lies immediately to the north, forms a narrow valley in which lies the ancient town of Sichem or Shechem. As seen from this point Gerizim is distinguished from its tamer neighbour by the boldness of its crags, the richness of its verdure, and the number of its springs. Its southern slope however is much gentler than its northern, and both are almost bare of trees. On the summit stands at present a small Mahometan chapel, and there are besides numerous traces of a fortress and church possibly dating from the time of Justinian. But the spot regarded by the Samaritans as the holiest upon earth is a small level plateau situated somewhat to the south of this. Here it is believed stood the temple built by Manasseh, the son of the Jewish high priest in the days of Nehemiah,³ and destroyed by John Hyrcanus 300 years afterwards (Jos., *Ant.*, xiii. 9 1). According to the Samaritans and some modern writers, Gerizim was the scene of the incidents recorded in Genesis xxii. 9–13. Probably as being the hill on the right hand of the spectator who, standing in the valley of Shechem, looks to the sun rising, it was also the hill on which, according to Josh. vii. 33, 34 (comp. Deut. xi. 29, 30, and xxvii. 12–26), after the conquest of Ai, the tribes of Simeon, Levi, Judah, Issachar, Joseph, and Benjamin stood to pronounce the blessings connected with a faithful observance of the law, while the remaining tribes from mount Ebal confirmed the curses attached to specified violations of the divine commands. According to Eusebius and Jerome indeed, the Ebal and Gerizim described in Deut. xi. 30 were not the mountains now known by that name, but two smaller hills in the neighbourhood of Jericho. This view, however, may now be regarded as universally abandoned (see Stanley, *Sinai and Palestine*, p. 236, note).

GERMAN CATHOLICS (DEUTSCHKATHOLIKEN), the name assumed in Germany towards the close of the year 1844 by certain dissentients from the church of Rome. The most prominent leader of the German Catholic movement was Johann Ronge, a Roman Catholic priest, who in October 1844 made a vigorous attack upon Arnoldi, bishop of Treves, for having made a relic, which he alleged to be the holy seamless coat of Christ, an object of pilgrimage and adoration. On Ronge's excommunication on this account, by the chapter of Breslau in December 1844, he received a large amount of public sympathy, and a dissenting congregation was almost immediately formed at Breslau with a very simple creed, in which the chief articles were belief in God the Father, creator and ruler of the universe; in Jesus Christ the Saviour, who delivers from the bondage of sin by his life, doctrine, and death; in the operation of the Holy Ghost; in a holy, universal, Christian church; in forgiveness of sins and the life everlasting. Within a very few weeks similar communities had been formed at Leipzig, Dresden, Berlin, Offenbach, Worms, Wiesbaden, and elsewhere; and at a “council” convened at Leipzig in March 1845, twenty-seven congregations were represented by delegates, of whom however only two or at most three were in clerical orders. Almost contemporaneously with the commencement of the agitation led by Ronge, another movement fundamentally distinct, though in some respects similar, had been originated at Schneidemühl, Posen, under the guidance of Johann Czerski, also a priest, who had come into collision with the church authorities on the then much discussed question of mixed marriages, and also on that of the celibacy of the clergy. The result had been his suspension from office in March 1844; his public withdrawal, along with twenty-four adherents, from the Roman communion in August; his excommunication im-

¹ See 1 Sam. xxvii. 8 (Keri.)

² Josephus (*Ant.*, xi. 8, 2) calls it the highest, but his assertion has been disproved by recent accurate measurement. According to Furrer, Tell 'Azur, Ebal, and Gerizim are 3666, 3375, and 3179 feet respectively above the level of the Mediterranean.

³ In the days of Alexander the Great, according to Josephus (*Ant.*, xi. 8, 2); but there are good reasons for believing this to be incorrect. See Neh. xiii. 28, and compare Bertheau on the passage.

mediately thereafter ; and the formation, in October, of a "Catholic Apostolic Christian" congregation which, while rejecting various practices of the Roman Church, retained the Nicene theology and the doctrine of the seven sacraments. Czernski had been at some of the sittings of the "German Catholic" council of Leipsic ; but when a formula somewhat similar to that of Breslau had been adopted, he refused to affix his signature because the divinity of Christ had been ignored, and he and his congregation continued to retain by preference the name of "Catholic Apostolic Christians" which they had originally assumed. Of the German Catholic congregations which had been represented at Leipsic some manifested a preference for the fuller and more positive creed of Schnoedemuhl, but a great majority continued to accept the comparatively negative theology of the Breslau school. The number of these increased with considerable rapidity, until in June 1846 in Silesia alone the members of the German Catholic communion were reckoned by thousands, while the congregations scattered over Germany amounted in all to 173. In Austria, however, and ultimately also in Bavaria, the use of the name German Catholics was officially prohibited, that of "Dissidents" being substituted, while in Prussia the adherents of the new creed were laid under various disabilities ; these and other circumstances, among which the frequent occurrence of internal dissensions was perhaps the gravest, conspired to check at an early stage the prosperous career of a movement which in its beginnings had been looked upon by many intelligent observers with considerable hopefulness. In 1859 some of the German Catholics entered into a union with the "Free Congregations," when the united body took the title of "The Religious Society of Free Congregations." Before that time many of the congregations which were formed in 1844 and the years immediately following had been dissolved, including that of Schnoedemuhl itself, which ceased to exist in 1857. No very recent statistics of a trustworthy kind as to the numerical strength of the German Catholics are accessible. Their total in Prussia was 6395 in 1861, and 10,930 in 1867, while in Saxony they numbered 1772 in 1849, and 3015 in 1871. At an early stage the movement attracted the attention of Gervinus, the eminent historian and critic, who in 1846 published a pamphlet entitled *Die Mission des Deutschkatholicismus*, to which, as well as to Kampfe's treatise *Das Ween des Deutschkatholicismus*, reference may be made. See also the article by Schmid in Herzog's *Realencyclopädie* (1878).

GERMANICUS, CÆSAR, a distinguished Roman general and provincial governor in the reign of Tiberius, was born 15 B.C., and died 19 A.D. His name Germanicus, the only one by which he is known in history, he inherited from his father Claudius Drusus Nero, the stepson of Augustus, and the most famous of his generals. His mother was the younger Antonia, the daughter of Marcus Antonius and niece of Augustus, and he married Agrippina the grand-daughter of the same emperor. It was natural that a prince so intimately allied both by birth and connexion with the reigning family should be regarded as a candidate for the purple. Augustus, it would seem, long hesitated whether he should name him as his successor, and as a compromise required Tiberius to adopt him, though Tiberius had a son of his own. When his uncle succeeded to the throne, Germanicus was the only rival that he feared ; and the emperor's jealousy and suspicion of him not only cut short his career of conquest but embittered the last years of his life, and precipitated, if it did not indirectly cause, his unhappy and premature end.

For the facts of his life our chief and, except a brief notice in Suetonius, almost our sole authority is Tacitus. Germanicus forms the central figure of the first two books

of the *Annals*, and in the minute and graphic record of his campaigns, the unravelling of the court intrigues to which he was subject, and the pathetic description of his last hours and of the outburst of grief and indignation which followed the news of his death, the historian has put forth all his powers. But a modern biographer, though compelled to trust to Tacitus for his materials, may yet be allowed to put upon them his own construction, to make allowance for the glamour which surrounded an amiable and ill-starred prince, and to discount the exaggerations of a master of rhetoric who has set his favourite hero in a blaze of light in order to deepen the shadows of his masterpiece Tiberius, the darkest and saddest portrait in all history. The following article will consist of a brief abstract of the life as related by Tacitus, and an estimate of the character as it presents itself to us in the foregoing records.

Of the early years and education of Germanicus little is known. That he possessed considerable literary abilities, and that these were carefully trained, we gather, not only from the speeches which Tacitus puts into his mouth, but from the reputation he left as an orator, as attested by Suetonius and Ovid, and from the fragments of his works which have survived. At the age of twenty he served his apprenticeship in the art of war under his uncle Tiberius, and was rewarded with the triumphal insignia for his services in crushing the revolt in Dalmatia and Pannonia. In 12 A.D. he was made consul, though he had neither attained the legal age nor passed through the grades of prætor and ædile. Soon afterwards he was appointed by Augustus to the important command of the eight legions on the Rhine. The news of the emperor's death found Germanicus at Lugdunum, where he was superintending the census of Gaul. Close upon this came the report that a mutiny had broken out among his legions on the lower Rhine. Germanicus hurried back to the camp, which was now in open insurrection. The tumult was with difficulty quelled, partly by well timed concessions for which the authority of the emperor was forged, but mostly by the help of his personal popularity with the troops. Some of the insurgents actually proposed that he should put himself at their head and secure for himself the empire, but their offer was rejected with righteous horror. In order to calm the excitement and prevent further disaffection, Germanicus determined at once on an active campaign. Crossing the Rhine at the head of 12,000 legionaries and an equal number of allied troops, he attacked and routed the Marsi, and laid waste the valley of the Ems. In the following year he marched against Arminius, the conqueror of Varus, and reached the fatal battlefield in the Teutoburg Forest. The bones of the Roman soldiers still lay bleaching on the ground near the altars where their tribunes had been immolated, and the gibbets where the prisoners had been hanged. Having performed the last rites and erected a barrow to mark the spot, he led his army on, breathing vengeance against the foe. Arminius, however, favoured by the marshy ground, was able to hold his own, and it required another campaign before he was finally defeated. A masterly combined movement by land and water enabled Germanicus to concentrate his forces against the main body of the Germans encamped on the Weser, and to crush them in two obstinately contested battles. A monument erected on the field proclaimed that the army of Tiberius had conquered every tribe between the Rhine and the Elbe. Great as the success of the Roman arms had been, it was not such as to justify this boastful inscription. We read of renewed attacks from the barbarians, and plans of a fourth campaign for the next summer.

But no more victories were in store for Germanicus. His success had already stirred the jealousy and fears of Tiberius, and he was reluctantly compelled to obey the imperial sum-

mons and repair to Rome. The magnificence of a triumph and the idle honours of a consulship had little attraction for a general in mid-career of conquest, and a man of singularly simple habits and no political ambition. The enthusiasm with which he was welcomed, not only by the populace, which went in crowds to meet him as far as the twentieth milestones, but by the emperor's own praetorians, warned Tiberius that it might be equally dangerous to keep so popular a favourite at Rome, and the earliest pretext was seized to remove him from the capital. The recent death of Archelaus, king of Cappadocia, and a disputed succession in Parthia and Armenia, afforded a sufficient plea for Roman interference, and, a few months after his return, Germanicus was despatched to the East with extraordinary powers, and started on his mission without waiting to enter on his consulship. At the same time Tiberius took the further precaution of superseding Silanus, a connexion of Germanicus, in the government of Syria, and appointing in his stead one of the most violent and ambitious of the old nobility, Cneius Calpurnius Piso, in order to watch his nephew's movements, and if necessary to check his ambition. Germanicus proceeded by easy stages to his province, halting on his way in Dalmatia, where he conferred with Drusus, his brother by adoption, and visiting the battlefield of Actium, Athens, Ilum, and other places of historic interest. At Rhodes he met for the first time his coadjutor Piso, who had followed in his wake, and was seeking everywhere to thwart his policy and asperse his character. When at last he reached his destination, he found little difficulty in effecting the settlement of the disturbed provinces, notwithstanding the violent and persistent opposition of Piso. At Artaxata Zeno, the popular candidate for the throne, was crowned king of Armenia, to the provinces of Cappadocia and Commagene Roman governors were assigned; and Parthia was conciliated by the banishment of the de throne king Vonones. After wintering in Syria Germanicus started next year for a tour in Egypt. The chief motive for his journey was love of travel and antiquarian study, and it seems never to have occurred to him, till he was warned by Tiberius, that he was thereby transgressing an unwritten law of the empire forbidding any Roman of rank to set foot in Egypt without express permission. On his return to Syria he found that all his arrangements had been upset by Piso. Violent recriminations followed, the result of which, it would seem, was a promise on the part of Piso to quit the province. But at this juncture Germanicus fell ill. Piso deferred his departure, and, when at length compelled to start, lingered in the neighbourhood of Syria, receiving with open exultation the bulletins which told of the prince's rapid decline. Germanicus on his side was fully convinced that he had fallen a victim to the arts of his unscrupulous enemy. He knew that he was dying, and believed that he was dying of poison. Even his gentle nature was stung to madness at the thought, and with his dying words he called on his friends and family to denounce his murderer and avenge his death. Whether these suspicions were true must remain an open question, yet the arguments in favour of a death from natural causes seem to preponderate. It is true that Piso desired his death, and, from what we know of their characters, neither he nor his wife Plancina were likely to stick at any means for procuring it. But a poisoner does not generally let his wishes be publicly known, nor show his exultation when they are attained. The evidence from the appearance of the corpse is still more uncertain. Suetonius indeed avouches that there were livid marks all over the body and foam at the mouth; but he adds as a further proof of poison that on the funeral pyre the heart remained unconsumed, which clearly shows that he was only retelling the vulgar gossip. Tacitus, though inclined to believe the worst of Piso, allows that the

report of the symptoms varied with the prepossession of the observers.

The sad tidings of his death cast a gloom over the whole Roman empire. To the provincials he had endeared himself by his simple manners, his affability, his generosity, his justice. The legions mourned their comrade who had always stood their friend in need, their general who had never known a defeat. At Rome there was a universal outburst of sorrow and indignation. The natural grief at the loss of a favourite prince was aggravated by the suspicion of foul play, and by hatred of the emperor who was at least guilty of recklessly exposing him to danger, and who now sullenly refused to join the general mourning. Men recalled the forboding words which had been whispered at his departure, "Whom the plebs love, die young." Nor was he unworthy of this passionate devotion. He had wiped out a great national disgrace; he had quelled their most formidable foe; he had pacified distant provinces, and in his high estate he had so borne himself that all save one man had loved and honoured him. His private life had been stainless, and he possessed in a singular degree the gift of personal attractiveness. And yet an impartial biographer must add that for his fair fame his death was opportune. There were elements of weakness in his character which his short life only half revealed: an almost feminine impetuosity which made him twice threaten to take his own life; a superstitious vein which impelled him to consult oracles and shrink from bad omens; an amiable dilettantism which led him to travel in Egypt while his enemy was plotting his ruin, a want of nerve and resolution which prevented him from coming to an open rupture with Piso till it was too late. His very virtues, his elegant taste, his chivalrous sense of honour, his unsuspecting openness and candour, unfitted him for the stern times in which he lived. He was as little fitted to play the part of Augustus as that of Alexander, to whom Tacitus fondly compares him; and had he lived to succeed to the purple the historian might have been compelled to pronounce on him the epitaph of Galba, that all would have thought him fit to reign if he had not reigned. (F. S.)

GERMAN SILVER, or NICKEL SILVER, known also under the names of White Copper and Packfong, is an alloy of copper, nickel, and zinc, prepared either by melting the copper and nickel together in a crucible, and adding piece by piece the previously heated zinc, or by heating the finely divided metals under a layer of charcoal, by means of an air furnace of strong draught, and promoting the thorough solution of the nickel by stirring. To destroy its crystalline structure, and so render it fit for working, it is heated to dull redness, and then allowed to cool. German silver is harder than silver; it resembles that metal in colour, but is of a greyer tinge. Exposed to the air it tarnishes slightly yellow, and with vinegar affords a crust of verdigris. At a bright red heat it melts, and with access of the atmosphere loses its zinc by oxidation. At a heat above dull redness it becomes exceedingly brittle. German silver is much used in the arts. For the manufacture of imitation silver for knives and forks its composition is—nickel and zinc of each 2 parts, and copper 4 parts; for handles of spoons and forks the proportion of copper in this formula is increased by 1. For rolling, the most suitable alloy is copper 3 parts, zinc 1, nickel 1. Candlesticks, bells, spurs, and other cast articles are made of a German silver containing 2 or 3 per cent. of lead. The addition of 2 to 2½ per cent. of iron, which must first be melted with part of the copper, makes an alloy which is whiter, but also more brittle and harder than ordinary German silver.

See COPPER, vol. vi. p. 351, and Watts, *Dict. of Chem.* ii. p. 51. On the electrical conductive capacity of German silver, see ELECTRICITY, vol. viii. p. 53.

GERMANY

PART I.—GEOGRAPHY AND STATISTICS.

GERMANY occupies the greater portion of central Europe, and has but few lines of natural boundary. If by the designation Germany is meant the territory inhabited by Germans, this is considerably larger than the German empire constituted in 1871, the former having an area of about 340,000, and the latter of 208,000 English square miles. The present German empire extends from 47° 16' to 55° 53' N. lat., and from 5° 52' to 22° 52' E. long. The eastern provinces project so far that the extent of the German territory is much greater from S.W. to N.E. than in any other direction. Tilsit is 815 miles from Metz, whereas Hadersleben, in Schleswig, is only 540 miles from the Lake of Constance. The difference in time between the eastern and western points is 1 hour and 8 minutes. The empire is bounded on the S.W. and S. by Austria and Switzerland (for 1170 miles), on the S.W. by France (275 miles), on the W. by Luxembourg, Belgium, and Holland (together 512 miles). The length of German coast on the North Sea or German Ocean is 300 miles, and on the Baltic 830 miles, the intervening land boundary on the north of Schleswig being only 53 miles. The eastern boundary is Russia (725 miles).

The total area of the empire, including rivers and lakes but not the "haffs" or lagoons on the Baltic, is 208,427 English square miles; which is about the 18th part of Europe, the 250th part of the whole dry land, and the 853d part of the whole surface of the globe.

PHYSICAL FEATURES.

Coast and Islands.—The length of the coast-line is scarcely the third part of the whole frontier, so that the Germans must be regarded as less a maritime than an inland people. Unlike the eastern states of Europe, the German empire has not only an inland sea-shore, but is also in direct communication with the great oceans by means of the North Sea. The coasts of Germany are shallow, and deficient in natural ports, except on the east of Schleswig-Holstein, where wide bays encroach upon the land, giving access to the largest vessels, so that a great harbour for men-of-war has been constructed at Kiel. With the exception of those on the east coast of Schleswig-Holstein, all the important trading ports of Germany are river ports, such as Emden, Bremen, Hamburg, Lübeck, Stettin, Dantzic, Königsberg, Memel. A great difference, however, is to be remarked between the coasts of the North Sea and those of the Baltic. On the former, where the sea has broken up the ranges of dunes formed in bygone times, and divided them into separate islands, the mainland has to be protected by massive dikes, while the Frisian Islands are being gradually washed away by the waters. On the coast of East Friesland there are now only seven of these islands, of which Norderney, a bathing-place, is best known, while of the North Frisian Islands, on the western coast of Schleswig, Sylt is the most considerable. Besides the ordinary waste of the shores, there have been extensive inundations by the sea within the historic period, the gulf of the Dollart having been so caused in the year 1276. Sands surround the whole coast of the North Sea to such an extent that the entrance to the ports is not practicable without the aid of pilots. Heligoland, which has belonged to England since 1814, is a rocky island, but it also has been

considerably reduced by the sea. The tides rise to the height of 12 or 13 feet in the Jähde Bay and at Bremerhafen, and 6 or 7 feet at Hamburg. The coast of the Baltic on the other hand possesses few islands, the chief being Alsen and Fehmarn off the coast of Schleswig-Holstein, and Rügen off Pomerania. It has no extensive sands, though on the whole very flat. The Baltic has no perceptible tides; and a great part of its coast-line is in winter covered with ice, which also so blocks up the harbours that navigation is interrupted for several months every year. Its three haffs fronting the mouths of the large rivers must be regarded as lagoons or extensions of the river beds, not as bays. The Oder Haff is separated from the sea by two islands, so that the river flows out by three mouths, the middle one (Svine) being the most considerable. The Frische Haff is formed by the Nogat, a branch of the Vistula, and by the Pregel, and communicates with the sea by means of the Pillau Tief. The Kurische Haff receives the Memel, called Niemen in Russia, and has its outlet in the extreme north at Memel. Long narrow alluvial strips called *Nehrungen*, lie between the last two haffs and the Baltic. The Baltic coast is further marked by large indentations, the Gulf of Lübeck, that of Pomerania, coast of Rügen, and the semicircular Bay of Dantzic between the promontories of Rixhöft and Briesterort. The German coasts are now well provided with lighthouses.

Surface and Geology.—In respect of physical structure Germany is divided into two entirely distinct portions, which bear to one another a ratio of about 3 to 4. The northern and larger part may be described as a uniform plain, covered generally by very recent deposits, but with small areas of Tertiary and Secondary formations protruding here and there. South and Central Germany, on the other hand, is very much diversified in scenery and in geological structure. It possesses large plateaus, such as that of Bavaria, which stretches away from the foot of the Alps, fertile low plains like that intersected by the Rhine, mountain chains, and isolated groups of mountains, comparatively low in height, and so situated as not seriously to interfere with communication either by road or by railway. Its geological structure corresponds to this diversity of surface. The most ancient rocks of Germany are the gneisses, schists, and granites which form the Bohemian and Bavarian plateau, and extend into Saxony. Another isolated mass of similar rocks rising into the heights of the Vosges and Black Forest has been cut through by the valley of the Rhine. Silurian rocks are but scantily developed in Germany. The Devonian system, however, occupies an extensive area, since it forms the high tableland of the Taunus, Hunsrück, and Eifel, which ranges westward into Belgium. Carboniferous rocks with productive coal-fields cover isolated areas, chiefly in north-western Germany, particularly in Westphalia, at Saarbrück, in Saxony, and in Upper and Lower Silesia (see COAL). Between the Devonian uplands of the Taunus and the crystalline rocks of Bavaria a vast area of western Germany is occupied by the Triassic system, which ranges from Hanover to Basel and from near Metz to Bairenth. The southern half of this vast Triassic basin is bordered by a belt of overlying Jurassic rocks which skirt the Danubian plain in Württemberg and Bavaria. Cretaceous rocks occur chiefly in north Germany in scattered patches flanking older formations. They evidently underlie the great plain, since they are found rising up here and there to the surface between Westphalia and

¹ 1 English square mile = 2.5899846 square kilometres, or 0.0470852 German square mile; 1 German square mile = 21.26067 English square miles; 1 sq. kilometre = 0.3861161 English square mile.

Denmark. Older Tertiary formations are absent from Germany, save the portion of the Eocene Alps included within the territory of Bavaria. But Miocene deposits extend into numerous detached basins, including those of the Rhine below Bonn, and at Mainz, the country round Magdeburg, and the plains of Bavaria. These strata contain valuable seams of lignite. The vast plains of northern Germany are covered with glacial drift, which rises to heights of 1400 feet above the sea along the edges of the flanking hills. Igneous rocks of different ages have been erupted in many districts, and further diversify the geology. The best known are the Tertiary and post-Tertiary lavas and cones of the Eifel and Siebengebirge, others of more ancient date occur along the southern slopes of the Harz.

Mountains and Plateaus.—Bavaria is the only division of the country that includes within it any part of the Alps, the Austro-Bavarian frontier running along the ridge of the Northern Tyrollese or Bavarian Alps. The loftiest peak of this group, the Zugspitze (57 miles south of Munich), is 9702 feet in height, being the highest summit in the empire. The Upper German plain sloping northwards from the Bavarian Alps is watered by the Lech, the Isar, and the Inn, tributaries of the Danube, all three rising beyond the limits of German territory. This plain is separated on the west from the Swiss plain by the Lake of Constance (Bodensee, 1306 feet above sea-level), and on the east from the undulating grounds of Austria by the Inn. The average height of the plain may be estimated at about 1800 feet, the valley of the Danube on its north border being from 1540 feet (at Ulm) to 920 feet (at Passau). The plain is not very fertile. In the upper part of the plain, towards the Alps, there are several lakes, the largest being the Ammersee, the Wurmsee or Starnberg Lake, and the Chiemsee. Many portions of the plain are covered by moors and swamps of large extent, there called *Moose*. The left or northern bank of the Danube, from Regensburg (Ratisbon) downwards presents a series of granitic rocks called the Bavarian Forest (Bayerischer Wald), which must be regarded as a branch of the Bohemian Forest (Böhmischer Wald). The latter is a range of wooded heights on the frontier of Bavaria and Bohemia, occupying the least known and least frequented regions of Germany. The summits of the Bayerischer Wald rise to the height of about 4000 feet, and those of the Bohemian Forest to 4800 feet, Hoher Arber, about 49° N. lat., being 4842 feet. The valley of the Danube above Ratisbon is flanked by Jurassic plateaus sloping gently to the Danube, but precipitous towards the valley of the Neckar. The centre of this elevated tract is the Raube Alp, so named on account of the harshness of the climate. The plateau continuing to the north-east and then to the north, under the name of the Franconian Jura, is crossed by the valley of the winding Altmühl, and extends to the Main. To the west extensive undulating grounds or low plateaus occupy the area between the Main and the Neckar.

The south western corner of the empire contains a series of better defined hill-ranges. Beginning with the Schwarzwald (Black Forest), we find its southern heights decline to the valley of the Rhine, above Basel, and to the Jura. The summits are rounded and covered with wood, the highest being the Feldberg (10 miles S.E. of Freiburg, 4902 feet). Northwards the Black Forest passes into the plateau of the Neckarbergland (average height, 1000 feet). The heights between the lower Neckar and the Main form the Odenwald (about 1700 feet); and the Spessart, which is watered by the Main on three sides, is nothing but a continuation of the Odenwald. West of this range of hills lies the valley of the upper Rhine, extending about 180 miles from south to north, and with a width of only 20 to 25 miles. In the upper

parts the Rhine is rapid, and therefore navigable with difficulty, this explains why the towns there are not along the banks of the river, but some 5 to 10 miles off. But from Speyer (Spres) town succeeds town as far down as Düsseldorf. The western boundary of this valley is formed in the first instance by the Vosges, where granite summits rise from under the surrounding red Triassic rocks (Sulzer Belchen, 4700 feet). To the south the range is not continuous with the Swiss Jura, the valley of the Rhine being connected here with the Rhone system by low ground known as the Gate of Mulhausen. The crest of the Vosges is pretty high and unbroken, the first convenient pass being near Zabern, which has been taken advantage of for the railway from Strasburg to Paris. On the northern side the Vosges are connected with the Haardt sandstone plateau (Kalmit, 2230 feet), which rises abruptly from the plain of the Rhine. The mountains south of Mainz (Mayence), which are mostly covered by vineyards, are lower, the Donnersberg, however, raising its head to 2262 feet. These hills are bordered on the west by the high plain of Lorraine and the coal-fields of Saarbrücken, the former being traversed by the river Moselle. The larger half of Lorraine belongs to France, but the German part possesses great mineral wealth in its rich layers of ironstone (sidente), and in the coal-fields of the Saar. The Devonian tract of the Hunsrück, Taunus, and Eifel is an extended plateau, divided into separate sections by the river valleys. Among these the Rhine valley from Bingen to Bonn, and that of the Moselle from Treves to Coblenz, are winding gorges excavated by the rivers. The Eifel presents a sterile, thinly-peopled plateau, covered by extensive moors in several places. It passes westwards imperceptibly into the Ardennes. The hills on the right bank of the Rhine also are in part of a like barren character, without wood; the Westerwald (about 2000 feet), which separates the valleys of the Sieg and Lahn, is particularly so. The northern and southern limits of the Niederhessisches Gebirge present a striking contrast to the central region. In the south the declivities of the Taunus (2890 feet) are marked by the occurrence of mineral springs, as at Ems on the Lahn, Naheim, Homburg, Soden, Wiesbaden, &c., and by the vineyards which produce the best Rhine wines. To the north of this Gebirge, on the other hand, lies the great coal basin of Westphalia (the largest in Germany). In the south of the hilly duchy of Hesse rise the isolated mountain groups of the Vogelsberg (2530 feet) and the Rhön (3117 feet), separated by the valley of the Fulda, which uniting further north with the Werra forms the Weser. To the east of Hesse lies Thuringia, a province consisting of the far-stretching wooded ridge of the Thüringer Wald (with three peaks of upwards of 3000 feet high), and an extensive elevated plain to the north. Its rivers are the Saale and Unstrut. This plateau is bounded on the north by the Harz, an isolated group of mountains, rich in minerals, with its highest elevation in the bare summit of the Brocken (3743 feet). To the west of the Harz a series of hilly tracts is comprised under the name of the Weser Mountains, out of which above Minden the river Weser bursts by the Porta Westphalica. A narrow ridge, the Teutoburger Wald (1300 feet), extends between the Weser and the Ems as far as the neighbourhood of Osnabrück.

To the east the Thüringer Wald is connected by the plateau of the Frankonwald with the Fichtelgebirge. This group of mountains, occupying what may be regarded as ethnologically the centre of Germany, forms a hydrographical centre, whence the Nab flows southward to the Danube, the Main westward to the Rhine, the Eger eastward to the Elbe, and the Saale northward, also into the Elbe. In the north-east the Fichtelgebirge connects itself directly with the Erzgebirge, which forms the northern boundary of Bohemia.

The southern sides of this range are comparatively steep, on the north it slopes gently down to the plains of Leipzig, but is intersected by the deep valleys of the Elster and Mulde. Although by no means fertile, the Erzgebirge is very thickly peopled, as various branches of industry have taken root there in numerous small places. Around Zwickau there is a productive coal-field, and mining for metals is carried on near Freiberg. In the east a tableland of sandstone, called Saxon Switzerland, from the picturesque outlines into which it has been eroded, adjoins the Erzgebirge; one of its most notable features is the deep ravine by which the Elbe escapes from it. Numerous quarries, which supply the North German cities with stone for buildings and monuments, have been opened along the valley. The sandstone range of the Elbe unites in the east with the low Lusatian group, along the east of which runs the best road from northern Germany to Bohemia. Then comes a range of lesser hills clustering together to form the frontier between Silesia and Bohemia. The most western group is the Isergebirge, and the next the Riesengebirge, a narrow ridge of about 20 miles' length, with bare summits. Excluding the Alps, the Schneekoppe (5266 feet) is the highest peak in Germany; and the southern declivities of this range contain the sources of the Elbe. The hills north and north-east of it are termed the Silesian Mountains. Here one of the minor coal-fields gives employment to a population grouped round a number of comparatively small centres. One of the main roads into Bohemia (the pass of Landsbut) runs along the eastern base of the Riesengebirge. Still farther to the east the mountains are grouped around the hollow of Glatz, whence the Neisse forces its way towards the north. This hollow is shut in on the east by the Sudetic group, in which the Altwater rises to almost 4900 feet. The eastern portion of the group, called the Gesenke, slopes gently away to the valley of the Oder, which affords an open route for the international traffic, like that through the Mulhausen Gate in Alsace. Geographers style this the Moravian Gate.

The North-German plain presents little variety, yet is not absolutely uniform. A row of low hills runs generally parallel to the mountain ranges already noticed, at a distance of 20 to 30 miles to the north. To these belongs the Upper Silesian coal-basin, which occupies a considerable area in south-eastern Silesia. North of the middle districts of the Elbe country the heights are called the Flaming hills. Westward lies as the last link in this series the Luneburger Heide or Heath, between the Weser and Elbe, north of Hanover. A second tract, of moderate elevation, sweeps round the Baltic, without, however, approaching its shores. This plateau contains a considerable number of lakes, and is divided into three portions by the Vistula and the Oder. The most easterly is the so-called Prussian Seenplatte. Spirdingsee (430 feet above sea-level, and 46 square miles in area) and Mauersee are the largest lakes; they are situated in the centre of the plateau, and give rise to the Pregel. Some peaks near the Russian frontier attain to 1000 feet. The Pomeranian Seenplatte, between the Vistula and the Oder, extends from S.W. to N.E., its greatest elevation being in the neighbourhood of Dantzic (Thurmberg, 1096 feet). The Seenplatte of Mecklenburg, on the other hand, stretches from S.E. to N.W., and most of its lakes, of which the Muriitzsee is the largest, send their waters towards the Elbe. The finely wooded heights which surround the bays of the east coast of Holstein and Schleswig may be regarded as a continuation of these Baltic elevations. The lowest parts, therefore, of the North-German plain, excluding the sea-coasts, are the central districts from about 52° to 53° N. lat., where the Vistula, Netze, Warthe, Oder, Spree, and Havel form vast swampy lowlands (in German called *Brüche*), which, during

the last hundred years, have been considerably reduced by the construction of canals and by cultivation,—improvements due in large measure to Frederick the Great. The Spreewald, to the S.E. of Berlin, is one of the most remarkable districts of Germany. As the Spree divides itself there into innumerable branches, enclosing thickly wooded islands, boats form the only means of communication. West of Berlin the Havel widens into what are called the Havel lakes, to which the environs of Potsdam owe their charms. In general the soil of the North-German plain cannot be termed fertile, the cultivation nearly everywhere requiring severe and constant labour. Long stretches of ground are covered by moors, and there turf-cutting forms the principal occupation of the inhabitants. The greatest extent of moorland is found in the westernmost parts of the plain, in Oldenburg and East Frisia. The plain contains, however, a few districts of the utmost fertility, particularly the tracts on the central Elbe, and the marsh lands on the west coast of Holstein and the north coast of Hanover, Oldenburg, and East Frisia, which, within the last two centuries, the inhabitants have reclaimed from the sea by means of immense dikes.

Rivers.—Nine independent river-systems may be distinguished those of the Memel, Pregel, Vistula (Weichsel), Oder, Elbe, Weser, Ems, Rhine, and Danube. Of these the Pregel, Weser, and Ems belong entirely, and the Oder mostly, to the German empire. The Danube has its sources on German soil; but only the fifth part of its course is German. Its total length is 1730 miles, and the Bavarian frontier at Passau, where the Inn joins it, is only 350 miles distant from its sources. It is navigable as far as Ulm, 220 miles above Passau; and its tributaries the Lech, Isar, Inn, and Altmühl are also navigable. The Rhine is the most important river of Germany, although neither its sources nor its mouths are within the limits of the empire. From the Lake of Constance to Basel (122 miles) the Rhine forms the boundary between the German empire and Switzerland; the canton of Schaffhausen, however, is situated on the northern bank of the river. From Basel to below Emmerich the Rhine belongs to the German empire—about 470 miles, or fourth-sevenths of its whole course. It is navigable all this distance, as are also the Neckar from Esslingen, the Main from Bamberg, the Lahn, the Lippe, the Ruhr, the Moselle from Metz, with its affluents the Saar and Sauer. Vessels sail up the Ems as far as Papenburg, and river craft as far as Greven, and the river is connected with a widely branching system of canals for turf-boats. The Fulda, navigable for 63 miles, and the Werra 38 miles, above the point where they unite, form by their junction the Weser, which has a course of 271 miles, and receives as navigable tributaries the Aller, the Leine from Hanover, and some smaller streams. Large steamers cannot, however, get as far as Bremen, and that commercial emporium has, in consequence, been obliged to form a seaport at Bremenhafen. The Elbe, after a course of 250 miles, enters German territory near Aussig, 482 miles from its mouth. It is navigable above this point to its junction with the Moldau. Hamburg may be reached by vessels of 10 to 11 feet draught. The navigable tributaries of the Elbe are the Saale (below Naumburg), the Havel, Spree, Elde, Sude, and some others. The Oder begins to be navigable almost on the frontier at Ratibor, 480 miles from its mouth, receiving as navigable tributaries the Glatz Neisse and the Wartha. Only the lower course of the Vistula belongs to the German empire, within which it is a broad, navigable stream of considerable volume. On the Pregel ships of 2500 tons reach Königsberg, and river barges reach Insterburg; the Alle, its tributary, may also be navigated. The Memel is navigable in its course of 113 miles from the Russian frontier. Germany is thus a country

abounding in natural waterways, the total length of them being estimated at 7000 miles. But it is only the Rhine, in its middle course, that has at all times sufficient volume of water to meet the requirements of a good navigable river.

Lakes.—The regions which abound in lakes have already been pointed out. The Bodensee or Lake of Constance (186 square miles) is on the frontier of the empire,—portions of the northern banks belonging severally to Bavaria, Württemberg, and Baden. The largest lake entirely on German territory is the Chiemsee (75 square miles); the Ammersee and the Wörnsee are, however, but little less. A good many smaller lakes are to be found in the Bavarian Alps. The North-German plain is dotted with upwards of 500 lakes, covering an area of about 2500 square miles. The largest of these are the three Haffs,—the Oderhaff covering 370 square miles, the Frische Haff 332, and the Karische Haff 326. The lakes in the Prussian and Pomeranian provinces, in Mecklenburg, and in Holstein, and those of the Havel, have already been mentioned. In the west the only lakes of importance are the Steinhuder Meer, 14 miles north-west of Hanover, and the Dümmersee on the southern frontier of Oldenburg.

Climate.—The climate of Germany is to be regarded as intermediate between the oceanic and continental climates of western and eastern Europe respectively. It has nothing in common with the Mediterranean climate of southern Europe, Germany being separated from that region by the lofty barrier of the Alps. Although there are very considerable differences in the range of temperature and the amount of rainfall throughout Germany, these are not so great as they would be were it not that the elevated plateaus and mountain chains are in the south, while the north is occupied by low-lying plains. In the west no chain of hills intercepts the warmer and moister winds which blow from the Atlantic, and these accordingly influence at times even the eastern regions of Germany. The mean annual temperature of south-western Germany, or the Rhine and Danube basins, has in recent years been about 52° to 54°, that of central Germany 48° to 50°, and that of the northern plain 46° to 48°. In Pomerania and West Prussia it is only 44° to 45°, and in East Prussia 42° to 44°. The warmest districts of the German empire are the northern parts of the Rhine plain, from Carlsruhe downwards, especially the Rheintal; these are scarcely 300 feet above the sea-level, and are protected by mountainous tracts of land. The same holds true of the valleys of the Neckar, Main, and Moselle. Hence the vine is everywhere cultivated in these districts. The mean summer temperature there is 68° and upwards, while the average temperature of January does not descend to the freezing point (32°). The climate of north-western Germany (west of the Elbe) shows a predominating oceanic character, the summers not being too hot (mean summer temperature 60° to 62°), and snow in winter remaining but a short time on the ground. West of the Weser the average temperature of January exceeds 32°; to the east it sinks to 30°, and therefore the Elbe is generally covered with ice for some months of the year, as are also its tributaries. The further one proceeds to the east the greater are the contrasts of summer and winter. While the average summer warmth of Germany is 60° to 62°, the January temperature falls as low as 26° to 28° in West Prussia, Posen, and Silesia, and 22° to 26° in East Prussia and Upper Silesia. The navigation of the rivers is regularly interrupted by frost. Similarly the upper basin of the Danube, or the Bavarian plain, has a rather inclement climate in winter, the average for January being 25° to 26°.

As regards rainfall, Germany belongs to those regions where atmospheric precipitation takes place at all seasons, but chiefly in the form of summer rains. In respect to the quantity of rain the empire takes a middle position

between the humidity of north-western Europe and the aridity of the east. There are considerable differences between particular places. The rainfall is greatest in the Bavarian table-land and the hilly regions of western Germany. For the Eifel, Sauerland, Harz, Thuringer Wald, Rhön, Vogelsberg, Spessart, the Black Forest, the Vosges, &c., the annual average may be stated at 34 inches or more, while in the lower terraces of south-western Germany, as in the Erzgebirge and the Sudetic range, it is estimated at 30 to 32 inches only. The same average obtains also on the humid north-west coast of Germany as far as Bremen and Hamburg. In the remaining parts of western Germany, on the shores of Further Pomerania, and in East Prussia, it amounts to upwards of 24 inches. In western Germany there is a district famous for the scarcity of rain, and for producing the best kind of wine: in the valley of the Rhine below Strasburg, in the Palatinat, and also in the valley of the Main, no more than from 16 to 20 inches fall. Mecklenburg, Brandenburg, and Lusatia, Saxony and the plateau of Thuringia, West Prussia, Posen, and Lower Silesia are also to be classed among the more arid regions of Germany, the annual rainfall being 16 to 20 inches.

VEGETATION, ANIMALS, AND AGRICULTURE.

The flora of Germany comprises about 3000 species of phanerogamic and about 4000 cryptogamic plants. The country does not, however, form a single natural region, and cannot be characterized distinctively by any of the principal botanical types.

No uniform returns for the whole empire have been published, furnishing details regarding the distribution of the soil in respect of its cultivation, and thus statistics can only be collected from the official returns and estimates or valuations for separate districts. The following tabular statements must therefore be regarded as only approximately accurate:—

Cultivable and Uncultivable Area.

States or Groups.	Cultivable.		Uncultivable.	
	Square Miles.	Percent of Total.	Square Miles.	Percent of Total.
Prussia, including the minor states of North Germany	134,400	61.7	12,130	8.3
Thuringia	4,450	93.7	300	6.3
Saxony	5,570	96.0	230	4.0
Bavaria	27,600	93.8	1,800	6.2
Württemberg	7,200	95.0	500	4.4
Baden	5,500	90.4	620	10.6
Alsace-Lorraine	6,200	90.9	520	9.1
Hesse	2,850	96.0	120	4.0
Total	192,370	92.3	10,650	7.7

Distribution of the Cultivable Area.

States.	Arable.		Meadows and Pasture Grounds.		Woodland.	
	Square Miles.	Percent of Total.	Square Miles.	Percent of Total.	Square Miles.	Percent of Total.
Prussia, &c.	74,150	60.7	26,870	16.8	20,380	22.7
Thuringia	2,600	62.6	440	9.8	1,510	31.8
Saxony	3,900	65.2	770	13.2	1,800	37.6
Bavaria	12,350	49.1	5,130	17.6	10,030	24.9
Württemberg	3,600	47.9	1,900	17.8	2,800	30.6
Baden	2,200	37.9	1,000	17.7	1,970	38.8
Alsace-Lorraine	2,770	48.6	600	11.6	1,770	20.9
Hesse	1,680	61.6	860	12.8	940	31.6
Total	102,800	49.0	36,870	17.6	65,000	29.7

From these tables it will be seen that the extent of uncultivable ground in Germany is inconsiderable; and that the arable land, including garden ground and vineyard amounts to about one-half of the area.

Forests.—The woodlands form about one-fourth of the entire soil, the proportion of forest being far greater than in any other state in the west or south of Europe; the percentage for France is but 17, for Italy 12, for Great Britain about 3. The state forests alone occupy 17,600 square miles; and the greatest attention is paid throughout the empire to forest culture. Speaking generally, northern is not nearly so well wooded as central and southern Germany, where indeed most of the smaller mountains are covered with timber, as is indicated by the frequent use of the termination *wald* affixed to the names of the mountain ranges (as Schwarzwald, Thüringer Wald, &c.). The "Seenplatten" are less wooded than the hill country, but the eastern portion of the northern lowlands is well provided with timber. A narrow strip along the shores of the Baltic is covered with oaks and beeches; further inland coniferous trees are the most prevalent, particularly the Scotch fir; birches are also abundant. The mountain forests consist chiefly of firs, pines, and larches, but contain also silver firs, beeches, and oaks. Chestnuts appear on the terraces of the Rhine valley, and in Swabia and Franconia. The whole north-west of Germany is destitute of wood, but to compensate for this the people have ample supplies of fuel in the extensive stretches of turf.

Agriculture.—The same kinds of cereal crops are cultivated in all parts of the empire, but in the south and west wheat is predominant, and in the north and east rye, oats, and barley. To these in some districts are added spelt, buckwheat, millet, rice-wheat (*Triticum dicoccum*), lesser spelt (*Triticum monococcum*), and maize. In general the soil is remarkably well cultivated. The three years' rotation formerly in use, where autumn and spring-sown grain and fallow succeeded each other, has now been abandoned, except in some districts, where the system has been modified and improved. In South Germany the so-called *Fruchtwechsel* is practised, the fields being sown with grain crops every second year, and with pease or beans, grasses, potatoes, turnips, &c., in the intermediate years. In North Germany the mixed *Koppelwirtschaft* is extending, by which system, after several years of grain crops, the ground is for two or three seasons in pasture. No general statistics on the subject of crops have as yet been published, but, according to private estimates, a fair average season will yield 325 million quarters of rye,¹ oats 300, wheat and spelt 170, barley 100. In good seasons the production has been found sufficient to meet the native demand. Formerly the exports of the produce of the wheat and pulse crops exceeded the imports, but the importation of cereals has now for a number of years been constantly increasing. The potato is largely cultivated, not merely for food, but for distillation into spirits. This manufacture is prosecuted especially in eastern Germany. The Prussian provinces east of the Elbe, including Mecklenburg and Saxony, with a population of about 19 millions, produced 72 million gallons² of spirits in 1876, while the rest of Germany (population 24 millions) produced only 25 million gallons. The common

the last thirty years. There are two centres of the beet-root sugar production: 231 factories, or more than two-thirds of the whole, are in Prussian Saxony, Hanover, Brunswick, Anhalt, and Thuringia, and there are 71 in Silesia, Brandenburg, and Pomerania, the principal centre of the latter group being Frankfort-on-the-Oder. Flax and hemp are cultivated, though not so much as formerly, for manufacture into linen and canvas, and also for the production of oil. The home supply no longer suffices for the native demand. The cultivation of hops is in a very thriving condition in the southern states of Germany. The soil occupied by hops was estimated in 1873 at 93,680 acres,³—a larger area than in any other country of the globe (Great Britain having about 70,000 acres). The total production of hops is 477,000 cwts., and of this 402,000 cwts. are grown in Bavaria, Württemberg, Baden, and Alsace-Lorraine. Hops thus form one of the standard articles of exportation from Germany, as well as beer. The following table shows the number of breweries in different parts of the country, and the amount of their production:—

States.	Breweries	Total Gallons	Per Head. Gallons.
Northern Germany.....	12,186	448,000,000	14
Bavaria, not including Palatinate.....	6,703	269,000,000	59
Palatinate (estimated)...		13,000,000	20
Württemberg.....	7,777	85,300,000	46
Baden (estimated).....	1,500	24,200,000	18
Alsace-Lorraine.....	241	17,600,000	11
Total, about.....	28,500	857,100,000	20

Tobacco forms the most productive and most profitable object of culture in many districts. The total extent under this crop in 1876 was 53,720 acres, no less than 32 per cent. of this being in Baden, 22 in Bavaria, 10 in Alsace-Lorraine, and only 30 per cent. in the rest of Germany. In the north the plant is cultivated principally in Pomerania, Brandenburg, and East and West Prussia. Of late years the production has on the whole diminished, the average amount having been 800,000 cwts. from 1872 to 1876.

The culture of the vine is almost confined to southern and western Germany, and especially to the Rhine district. The northern limits of its growth extend from Bonn in a north-easterly direction through Cassel to the southern foot of the Harz, crossing 52° N. lat. on the Elbe, running then east some miles to the north of that parallel, and finally turning sharply towards the south-west on the Warthe. In the valley of the Saale and Elbe (near Dresden), and in Lower Silesia (between Guben and Grünberg), the number of vineyards is small, and the wines of inferior quality; but along the Rhine from Basel to Coblenz, in Alsace, Baden, the Palatinate, and Hesse, and above all in the province of Nassau, the lower slopes of the hills are literally covered with vines. Here are produced the celebrated Rudesheimer, Hochheimer, and Johannisberger. The vines of the lower Main, particularly those of Würzburg, are the best kinds; those of the upper Main and the valley of the Neckar are rather inferior. The Moselle wines are lighter and more acid than those of the Rhine. The total amount produced in Germany is estimated at 1000 million gallons.—Alsace-Lorraine turning out 400 millions, Baden 175, Bavaria, Württemberg, and Hesse together 300, while the remainder, which though small in quantity is in quality the best, is produced by Prussia.

Livestock.—The cultivation of grazing lands in Germany has been greatly improved in recent times, and is in a highly prosperous condition. The provinces of Pomerania

Years.	Manu- factories.	Beet-root con- sumed.	Sugar produced
1846-47	107	5,900,000	831,000
1856-57	233	27,500,000	1,800,000
1866-67	296	50,700,000	3,900,000
1874-75	333	55,100,000	5,100,000
1875-76	332	83,200,000	7,100,000
1876-77	328	71,000,000	5,800,000

beet (*Beta vulgaris*) is largely grown in some districts for the production of sugar, which has greatly increased during

¹ 1 quarter = 2·90781 hectolitres; 1 hectolitre = 0·34888 quarter.

² 1 gallon = 0·22 litre.

³ 1 acre = 0·40467 hectare; 1 hectare = 2·4711442 acres.

and Hanover are particularly remarkable in this respect. The best meadow lands of Bavaria are in the outer range of the Alps, those of Saxony in the Erzgebirge. The following table shows the results of a live-stock census in 1873:—

Horses	3,352,281
Cattle	15,776,702
Sheep	24,999,406
Pigs	7,124,088
Goats	2,320,002

Total 53,572,429

The breeding of domestic animals is prosecuted most extensively in Bavaria, and in the maritime provinces. There we find 1000 to 1500 head of the larger kinds (horses, cattle, sheep, goats, swine) for every 1000 inhabitants; in the rest of eastern Germany 600 to 800, and in central and southern Germany only 400 to 600. In the number of horses Germany ranks with Great Britain (about 80 for every 1000 inhabitants); and, although the production cannot satisfy the home demand, the imports being nearly 30,000 in excess of the exports annually, the breeding of horses has attained great perfection. The main centre is in East and West Prussia, where there are more than half a million of horses,—about 30 per English square mile; then follow the marsh districts on the Elbe and Weser, some parts of Westphalia, Saxony, and Upper Silesia, Lower Bavaria, Lower Alsace, and Lorraine. Cattle abound in most South-German states, especially Bavaria and Württemberg, where there are 180 to 200 head for every square mile. In the northern and north-eastern districts, on the other hand, the numbers are small (in some districts only 30 to 50 head to the square mile), except Schleswig-Holstein and the marsh lands along the shores of the North Sea, whence there is a considerable exportation to England. The aggregate number of sheep in Germany is only exceeded in Europe by that in Great Britain and Russia. The principal sheep districts are Pomerania and Mecklenburg (800 per square mile). As a rule, sheep-farming is resorted to where the soil is of inferior quality and unsuitable for tillage and the breeding of cattle. Far more attention is accordingly given to the rearing of sheep in northern and north-eastern Germany than in Schleswig-Holstein, East Frisia, Westphalia, Rhineland, and South Germany. The exportation of sheep is considerable, amounting in 1871 to 1,460,000 head, in 1875, however, the number was only 1,000,000. At the same time the native demand for wool is not covered by the home production. The largest stock of swine is in central Germany and Saxony, in Westphalia, on the lower Rhine, in Lorraine, Hesse, &c. Central Germany (especially Gotha and Brunswick) exports sausages and hams largely, as well as Westphalia, but the excess of swine imported over the exports for the whole of Germany ranges from 600,000 to 800,000 annually.

Agricultural Population.—In the census returns of 1871 the number of persons entered as agriculturists (including persons engaged in rearing stock, in forestry, and the fisheries) was about 12,210,000, comprising 1,844,202 proprietors (1,690,931 males and 153,271 females), 2,101,005 agricultural labourers, &c., with 6,764,747 members of their families (2,338,174 males and 4,426,573 females), and about 1,500,000 (660,000 males and 840,000 females) engaged in household duties. Agriculture thus supports three-tenths of the population.

Wild Animals.—The number of wild animals in Germany is not very great. Foxes, martens, weasels, badgers, and otters are to be found everywhere; wolves are rare, but they find their way sometimes from French territory to the western provinces, or from Poland to Prussia and Posen. Among the rodents the hamster and the field-mouse are a source to agriculture. Of game there are the roe, stag,

boar, and hare; the fallow deer and the wild rabbit are less common. The elk is to be found in the forests of East Prussia. The feathered tribes are everywhere abundant in the fields, woods, and marshes. Wild geese and ducks, grouse, partridges, snipes, woodcocks, quails, widgeons, and teal are plentiful all over the country. Geese and ducks are found mostly in the flat districts, where the great abundance of standing water affords ample scope for their increase. Tame geese are bred in large flocks, particularly in Pomerania. The length of time that birds of passage remain in Germany differs considerably with the different species. The stork is seen for about 170 days, the house-swallow 160, the snow-goose 260, the snipe 220. In northern Germany these birds arrive from twenty to thirty days later than in the south.

The waters of Germany abound with fish; but the genera and species are few. Carp and salmon tribes are the most abundant; after them rank the pike, the eel, the shad, the roach, the perch, and the lamprey. In addition to frogs, Germany has few varieties of Amphibia. Of serpents there are only two kinds, one of them being poisonous.

The rearing of bees is particularly attended to in the healthy districts of Hanover. The number of bee-hives may be estimated at 2 millions, and the produce of wax and honey at 100,000 cwts. The cultivation of silk-worms has been attempted, but has either entirely failed or had very indifferent success. In 1852–62 an attempt was made to extend the cultivation of the mulberry in the province of Brandenburg, but disease among the silk-worms, which it was found impossible to repress, rendered it unsuccessful.

MINES AND MINERALS.

Germany abounds in useful minerals, and in consequence takes a high place among industrial states. The production falls short, indeed, of that of England, but bears comparison with that of France and of the United States. The last annual report of the imperial statistical office (for the year 1876) classified the mineral produce of Germany under the following heads:—

Mineral Production in 1876.

Minerals	Quantities.	Value.	Minors
	Metric Tons. ¹	£	
Coal, including lignite ..	49,559,050	15,131,000	208,429
Iron ore	3,615,020	1,047,850	24,373
Zinc ore	593,360	650,840	11,680
Lead ore	12,060	1,019,300	16,629
Copper ore	30,450	356,260	7,077
Silver and gold ore	2,311	219,150	7,475
Tin ore	185	6,880	306
Cobalt ore	313	10,000	...
Nickel ore	1,222	5,780	100
Antimony ore	433	650	60
Arsenic ore	1,670	2,610	20
Manganese ore	11,651	28,240	79
Bismuth ore	28	13,060	824
Uranium ore	9	2,210	...
Tungsten ore	3	20	...
Iron pyrites	113,703	107,290	...
Alum ores	35,320	4,400	829
Salt	170,150	60,700	198
Potash, &c.	580,900	234,500	2,053
Total, about	55,000,000	18,900,000	280,401

The general value of the production has increased considerably during the ten years ending 1876, as will be seen by the following table:—

¹ 1 centner or 50 kilogrammes = 110·23 pounds = 0·9851 cwt. In round numbers the centner is taken as equivalent to the cwt., and the metric ton to the English ton; the exact value of the latter, however, is 19 702 cwts., or 0·9851 tons. £1 sterling = 20·4294 marks. In round numbers £1 is taken as 20 marks; the values given are therefore too large by 2·15 per cent.

	Not including Lorraine.	£		£
1867		10,790,700	1872	20,783,000
1868		11,248,000	1873	25,732,000
1869		12,021,000	1874	25,383,000
1870		12,412,000	1875	20,844,000
1871		15,708,000	1876	18,900,000

The metals extracted from ores in 1876 were thus classified.—

Metal Production in 1876.

Metals		Quantities.	Value
		Cwts.	£

Coal.—Coal-mining appears to have been first practised in the 14th century, at Zwickau (Saxony), and on the Ruhr. The production, which certainly did not exceed 500,000 tons in 1800, has vastly increased during the last thirty years, as may be seen from the following table (which does not include lignite):—

Coal Production, 1848-1877.

	Quantities.	Value
	Metric Tons.	£
1848	4,384,000	1,284,000
1853	8,829,000	2,566,000
1857	11,279,000	4,137,000
1862	15,576,000	4,155,000
1867	23,808,000	6,871,000
1871	29,993,000	10,917,000
1872	33,306,000	14,383,000
1873	36,392,000	20,183,000
1874	35,919,000	19,859,000
1875	37,496,000	14,874,000
1876	38,454,000	13,184,000
1877	37,576,000	10,854,000

There are six large coal-fields, occupying an area of about 3600 square miles, of which the most important occupies the basin of the Ruhr, its extent being estimated at 2800 square miles. Here there are more than 60 beds, of a total thickness of 150 to 200 feet of coal; and the amount in the pits has been estimated at 45,000 millions of tons, so that the basin, at the present rate of 17,500,000 tons raised per annum, would not be exhausted in 2000 years. Smaller fields are found near Osnabrück, Ibbenbüren, and Minden, and a larger one near Aix-la-Chapelle. The Saar coal-field, within the area enclosed by the rivers Saar, Nahe, and Blies (460 square miles), is one of great importance. The thickness of 80 beds amounts to 250 feet, and Von Dechen estimates the total mass of coal at 45,400 million tons. The

greater part of the basin belongs to Prussia, the rest to Lorraine. A still larger field exists in the Upper Silesian basin, on the border-land between Austria and Poland, containing about 80,000 million tons. Beuthen is the chief centre. The Silesian coal-fields have a second centre in Waldenburg, east of the Riesengebirge. The Saxon coal-fields stretch eastwards for some miles from Zwickau. Deposits of less consequence are found in Upper Bavaria, Upper Franconia, Baden, in the Harz, &c.

Number and Production of Collieries in 1876

Coal-Fields (Not including Lignite)	Number of Collieries	Coal produced in 1876.
		Tons.
Ruhr (gov. districts, Arns- berg and Düsseldorf) ..	207	17,430,000
Upper Silesia	107	8,468,000
Saar	83	5,080,000
Zwickau	71	3,038,000
Lower Silesia	44	2,180,000
Aix-la-Chapelle	17	994,000
Osnabrück, Ibbenbüren, &c.	22	832,000
Minor fields	47	472,000
Total	548	38,454,000

The above tables do not include lignite, of which numerous beds are scattered over Germany. Extensive strata follow the course of the Oder, and a second group is spread over Lusatia, but the largest and most important deposit is in the Saale districts from Altenburg to the Harz. Smaller fields are situated round Cassel, northward of Frankfurt, near Cologne and Aix-la-Chapelle, in the west of Hanover, and in the Upper Palatinate. The total production is stated in the official returns at 11,100,000 tons, representing a value of £1,922,000. Of this 8,780,000 tons are supplied by the fields in the Saale districts (province of Saxony, Anhalt, Brunswick, Saxe-Altenburg, and kingdom of Saxony). In North Germany turf also is of importance as a fuel; the area of the turf moors in Prussia is estimated at 8000 square miles, of which more than 2000 are in the north of Hanover. The coal produced supplies the home demand, although a considerable trade is carried on across the frontier. Through the ports of the North Sea and the Baltic more than 2 million tons of coals are imported annually from England, and nearly 2½ million tons of lignite come from Bohemia. On the other hand, the Ruhr and the Saar basins export nearly 3 million tons of coal to the Netherlands, France, and Switzerland, and the Upper Silesian basin 1½ millions to Austria and Russia. The following table gives a comparative view of the quantity supplied by the more important coal-producing countries in 1876:—

	Tons		Tons.
Great Britain	135,812,000	France	18,889,000
United States	50,000,000	Belgium	14,329,000
Germany	48,296,000	Austria-Hungary ..	13,862,000

Graphite is produced only in Lower Bavaria; the total amount in 1876 was 20,104 cwts., value £2090. **Asphalt** occurs near Hanover, in Brunswick, and in Alsace; total production in 1876, 720,000 cwts., value £15,300. **Petroleum** is found in limited quantity near Lüneburg, and in Alsace.

Iron Ore.—Germany abounds in iron ores, some of which are of superior quality. The production increased rapidly for a time, but in recent years there has been a very great decline.

About 35 per cent. is brown iron ore, 25 per cent. spathic iron, 18 per cent. black band, and 10 per cent. red iron ore. The rest consists of clay-ironstone, bog-iron ore (in the northern lowlands), and magnetic ores. Unfortunately but few mines are found in proximity to coal-pits, and important ore-deposits of great extent are far from coal, as, for

instance, the iron districts of Nassau, of the Sieg valley, and of Hesse, Thuringia, Lorraine, Bavaria, and Württemberg.

Iron Ore Production, 1848-1876.

	Quantities.		Value.
	Tons	£	
1848 } Lorraine	694,000	191,000	
1853 } not	903,000	250,000	
1857 } included.	1,982,000	588,000	
1867	3,264,000	918,000	
1872	5,896,000	2,118,000	
1873	6,177,000	2,117,000	
1874	5,137,000	1,430,000	
1875	4,739,000	1,387,000	
1876	4,712,000	1,181,000	

Ores free of phosphorus, suitable for the manufacture of Bessemer pig-iron, are also very scarce.

The following table shows the number and production of furnaces in blast in 1876 :—

Government Districts.	Furnaces in Blast	Pig-iron made.
		Tons
Arnsberg	37	387,640
Düsseldorf	21	278,110
Oppeln	32	228,750
Coblenz	27	212,470
Lorraine	18	193,450
Treves	10	103,080
Hildesheim	4	55,750
Osnabrück	4	45,200
Upper Palatinate	10	31,060
Wiesbaden	14	28,550
Cologne	3	25,130
Hesse (grand-duchy)	5	18,150
Württemberg	5	10,810
Saxe-Meiningen	1	13,840
Other districts	34	37,690
Total	225	1,614,680

The iron manufacture has not been in a thriving condition since 1873; the total number of furnaces in Germany in 1876 was 435,—225 in blast as above, and 210 blown out. The following table shows the progress of pig-iron production, including castings :—

	Quantities.		Value
	Tons.	£	
1848 } about	200,000	1,230,000	
1862 }	640,000	2,630,000	
1867 }	990,000	3,000,000	
1871 }	1,421,000	5,940,000	
1873 }	1,938,000	11,298,000	
1874 }	1,660,000	7,243,000	
1875 }	1,759,000	6,632,900	
1876 }	1,615,000	5,232,000	

Since the incorporation of Lorraine with the German empire the pig-iron production of Germany exceeds that of France. The following table shows the comparative increase in those countries, as well as in Great Britain and the United States :—

	Quantities of Pig-Iron.			
		Tons.		Tons.
Great Britain ...	1866	4,596,000	1876	6,660,000
United States ...	"	1,225,000	1877	2,351,000
Germany	"	1,000,000	1876	1,615,000
France	"	1,260,000	1877	1,453,000

Iron Industry.—While the produce of pig-iron has thus been advancing, similar progress appears in the iron industry, in some branches of which Germany has already emancipated herself from dependence on England. During the last few years, it is true, this trade has suffered

severely from the overproduction of 1872 and 1873, as may be seen from the following table, showing the quantities and values of worked pig-iron in 1872 and 1876 :—

Articles	1872.		1876	
	Quantities	Value	Quantities	Value.
	Cwts	£	Cwts	£
Wrought iron & rolled iron	19,194,000	12,255,000	15,515,000	5,018,000
Iron plate	2,348,000	2,007,000	2,190,000	1,095,000
Iron wire	2,053,000	1,999,000	2,650,000	1,892,000
Raw steel	2,708,000	2,333,000	2,880,000	1,104,000
Cast steel	3,542,000	2,840,000	4,877,000	2,488,000

The greatest advance has been made in the production of steel. In 1863 the quantity was only 1,400,000 cwts., but in 1872 it was about 6,500,000. The greater part of this is produced at the celebrated works of Krupp in Essen and the cast-steel works in Bochum. Many European states have for a considerable time been supplied by Krupp with cast-steel guns. The production of rails not only covers the home demand, but has allowed an annual exportation of 3,000,000 cwts. since 1877. Hardware also, the production of which is centred in Solingen, Heilbronn, Esslingen, &c., is largely exported. Germany stands second to Great Britain in the manufacture of machines and engines. There are in many large cities of North Germany extensive establishments for this purpose, but the industry is not limited to the large cities. It must be admitted that in agricultural machinery Germany cannot as yet compete with England. The locomotives and waggons for the German railways, however, are almost exclusively built in Germany; and Russia, as well as Austria, receives large supplies of railway plant from German works. In shipbuilding likewise Germany is becoming independent of England; and dockyards have been erected on the coast for the construction of large ironclads.

Silver and Gold.—Germany produces more silver than any other European state, and the quantity is annually increasing. Silver and gold are extracted from the ores in the mines of Freiberg (Saxony) and near the Harz; but silver is also refined from lead and copper ores in Upper Silesia, Merseburg, Aix-la-Chapelle, Wiesbaden, and Arnsberg. The gold-mining is of far less importance. The value of silver produced was, in 1867, £791,370; 1873, £1,539,590; 1876, £1,098,470; and that of gold, 1867, £11,750; 1876, £39,234.

Lead.—The quantity of the lead produced allows Germany to export from 300,000 to 400,000 cwts. annually. Nearly half the produce is obtained near Aix-la-Chapelle (651,273 cwts. in 1876); next come Upper Silesia (265,000 cwts.), Harz (176,550 cwts.), Nassau (143,770 cwts.), Saxony, Arnsberg, &c. The value in 1867 was only £898,140; but in 1876, £1,563,280; the quantity was 987,090 cwts. in 1867, and 1,512,000 cwts. in 1876.

Copper.—Although Germany yields more copper than any other European state, the native supply does not meet the demand. In recent years more than 200,000 cwts. have been imported. The Harz mountains and their environs (Mansfeld) alone produce five-sixths of the whole amount, which has been doubled during the ten years ending 1876—1867, 77,440 cwts., value £312,750; 1876, 108,430 cwts., value £641,750.

Zinc.—About 90 per cent. of the zinc produced in Europe is yielded by Belgium and Germany. The exportation from the latter amounts to more than half a million of cwts. per annum. The production doubled during the period from 1850 (620,000 cwts.) to 1860, but has made only slow progress since that time. In 1867 it was only 1,277,000

cwts., value about £600,000, in 1876, 1,664,500, value £1,740,600. 70 per cent. is produced in Upper Silesia in the neighbourhood of Beuthen, the rest in Westphalia and the Rhineland.

Salt.—Germany possesses abundant salt deposits. The actual production not only covers the home consumption, but also allows a yearly increasing exportation, especially to Russia, Austria, and Scandinavia. In 1877-78 there were 77 salt works in operation, 8 of which were mining works for rock-salt. The provinces of Saxony and Hanover, with Thuringia and Anhalt, have 28 works, and produce half the whole amount. A large work is found at Strzalkowo (Posen), and smaller ones near Dortmund, Lippstadt, and Minden (Westphalia). In South Germany salt abounds most in Württemberg (Hall, Heilbronn, Rottweil); the principal Bavarian works are at the foot of the Alps near Freilassing and Rosenheim. Hesse and Baden have 6 salt works; Lorraine and the Upper Palatinate, 6. The total yield now amounts to 8,318,000 cwts. boiled salt, 3,221,000 cwts. rock salt, and 256,000 cwts. of other kinds. The production has made great advance during the last thirty years, having in 1850 been only 5 million cwts., while in 1877 it was upwards of 11 million cwts.

Chloride of Potash.—A considerable amount of this substance is turned out by 15 works in Anhalt, where only the potash ores are found. The production there in 1876 was 846,000 cwts., value about £250,000.

POPULATION.

Till very recent times no estimate of the population of Germany was precise enough to be of any value. At the beginning of the present century the country was divided into some hundred states, but there was no central agency for instituting an exact census on a uniform plan. Even the formation of the German Confederation in 1815 effected but little change in this respect, and it was left to the different states to arrange in what manner the census should be taken. On the formation, however, of the German Customs Union or Zollverein between certain German states, the necessity for accurate statistics became apparent, since the amounts accruing from the common import duties were to be distributed according to the number of inhabitants in the several states. The Zollverein had its origin in a customs convention between Prussia and the grand-duchy of Hesse in 1828; and other states, as they gradually became convinced of the advantages afforded by a general customs frontier, joined it from time to time during the succeeding forty years. The following table shows the progressive territorial limits of the Zollverein—which may be regarded as the precursor of the present German empire:—

Population of the Zollverein.

Years.	States entering during the various Periods.	Area, Sq. Miles.	Population of the Union States.
1828	Prussia, Hesse (grand-duchy)	112,000	13,295,254
1831	Hesse-Cassel	115,800	15,090,075 ('84)
1834	Bavaria, Württemberg, Saxony, Thuringia, &c.	163,900	23,478,120
1844	Brunswick, Luxembourg, &c.	171,900	28,498,136 ('43)
1851	Hanover, Oldenburg	191,800	32,569,055 ('52)
1868	Schleswig-Holstein, Lauenburg, Mecklenburg	205,500	38,277,939 ('67)
1871	Alsace-Lorraine	209,281	40,677,950

The returns made at different times by the separate states cannot be combined into an aggregate, showing precisely the former population of Germany. An enumeration was made every third year of the number of people that could be held as belonging to the different states

comprised in the Zollverein; and it was only from 1867 that the returns gave the actual resident population. The following table gives the area and population of the twenty-six states of Germany as returned at the two last censuses (1871 and 1875):—

Population of the German Empire, 1871 and 1875.

States of the Empire	Area, English Sq. Miles	Population	
		Dec 3, 1871	Dec 1, 1875.
<i>Kingdoms</i>			
1 Prussia	184,178	24,691,433	25,742,404

24 Bremen	109	52,158	56,912
25 Hamburg	97	122,402	142,200
<i>Imperial Territory</i>			
26 Alsace-Lorraine	153	388,974	385,618
<i>Imperial Territory</i>			
26 Alsace-Lorraine	5,608	1,549,738	1,581,804
Total	208,425	41,058,792	42,727,330

The following table shows the rate of recent increase, the population of Alsace-Lorraine returned at the French census of 1866 being included in the statement for 1867.—

Years	Population	Total Increase	Percentage for the period.	Percentage per annum.
Dec. 3, 1867	40,108,029			
Dec. 3, 1871	41,058,792	950,763	2·4	0·6
Dec. 1, 1875	42,727,360	1,688,568	4·1	1·0

Comparing the census returns of 1871 and 1875, it is found that only Alsace-Lorraine (17,934), the two Mecklenburgs (together 5231), and Waldeck (1481) are decreasing; all other states are increasing, though at very different rates. A comparison cannot here be made, however, between the smaller and the larger states. Hamburg and Bremen, for example, have considerably increased, but these must be regarded as consisting of single large towns, and a similar increase is found in all the great cities of Germany. In southern Germany (Alsace-Lorraine not included), and also in Hanover, the growth of population has been insignificant, whereas the population in the eight old provinces of Prussia and in Saxony shows a marked increase.

It appears from the following table that the inhabitants of Prussia and Saxony have increased 60 to 70 per cent. in 40 to 44 years, and those of the other states only 18 to 23 per cent. And it is to be observed that this increase is not confined to the industrial districts, but that those provinces also which have few large cities and the population of which live for the most part by agriculture, such as

Pomerania, Prussia, Posen, have increased by 50 to 60 per cent. This is to be explained by the fact that there has been a very extensive immigration into Prussia since 1815, whereas emigration has been mostly from South Germany. But the surplus of births over deaths also has at all times been greater in the North.

Increase of Population in States.

Provinces or States.	Population		Total Increase per cent
	Census 1831-34	Census 1875	
Saxony (kingdom)	(34) 1,590,000	2,760,000	73
The eight ancient Prus provinces	(31) 13,040,000	21,116,000	62

Vital Statistics.—It is very recently that general registers of births, deaths, and marriages began to be kept for all the German states, but these prove the increase of the excess of births over deaths in recent years to have been considerable. The following table of returns for the whole of Germany during the period 1872-78 brings out a natural addition by births of upwards of half a million yearly:—

	Marriages	Births (incl. Still born)	Deaths (incl. Still born)	Still-born	Surplus of Births.
1872	423,900	1,692,287	1,200,922	66,180	431,805
1873	416,049	1,716,287	1,241,459	67,108	474,019
1874	400,282	1,759,978	1,191,132	69,586	560,576
1875	388,748	1,798,591	1,246,572	74,179	552,019
1876	366,912	1,831,213	1,207,144	78,517	624,074
Mean...	398,778	1,758,059	1,229,806	70,117	528,878

The numbers of births, deaths, and marriages for every 1000 of the population of Germany during the period 1872-5 were as follows:—

	To 1000 Persons living.			To 1000 Marriageable Persons	
	Births.	Deaths	Marriages	Births	Marriages
1872	41.1	30.5	10.3	39.9	
1873	41.3	29.9	10.0	37.8	
1874	41.8	28.4	9.5	36.0	
1875	42.3	29.3	9.1	34.3	
Mean...	41.6	29.5	9.7	36.7	

In comparing this with similar tables for England, a great difference is obvious. While the average annual rate of births (41.6) has been much higher than in England (34.0) during recent years, the annual death-rate does not compare favourably with that of England (22.3) or of other states. Only Russia, Finland, Austria-Hungary, Italy, and Servia exhibit greater higher rates.

Sexes.—The numbers of the different sexes in 1871 and 1875 were as follows:—

	Males.	Females.	Excess of Females	Females for 1000 Males.
1871	20,154,109	20,906,787	752,688	1087
1875	20,986,701	21,740,659	753,958	1086

As in most European states, the surplus of females arises from their lower death-rate, for in Germany as elsewhere more boys are born than girls. The following table shows the numbers of births, including still-born:—

	Boys	Girls.	Excess of Boys	Boys for 1000 Girls
1872	871,438	890,786	50,652	1062
1873	883,017	892,265	50,752	1061
1874	903,148	849,821	53,327	1063
1875	928,397	870,194	58,203	1067
1876	943,433	887,781	55,652	1068
Average	905,837	852,170	53,717	1063

Illegitimacy.—The number of illegitimate births is greater than in any other European state, except Sweden, Denmark, Austria, and Portugal. The rate of illegitimacy is about 9 per cent. of the births, the annual average for 1872-75 being 8.86. In Rhineland the proportion was 2.8 per cent., North-Western Germany, Oppeln, and Posen 5 to 6, South-Western Germany 7 to 9, province of Saxony, Brandenburg (exclusive of Berlin), Pomerania, Schleswig-Holstein 9 to 10, Saxony, Thuringia, and Lower Silesia 12, Berlin 13.5, and Bavaria 14.6 per cent. On the whole, illegitimacy has decreased of late, particularly in Bavaria.

Emigration.—The increase of population would have been still greater if emigration had not for years drained the country of considerable numbers of its inhabitants. The number of emigrants from Germany since 1820 may be estimated at 3,500,000, but this includes many Austrians, and it cannot be stated how many of the emigrants were natives of the German empire, as no authentic statistics of emigration were issued before 1873. The greater part of the emigrants take their passage via Bremen and Hamburg. The following statement, therefore, of the numbers of emigrants from these ports may afford a sufficient indication of the total emigration:—

	Emigrants	Emigrants.
Average		
1836-44	14,653	1870 70,337
1845-49	36,706	1871 102,740
1850-54	77,165	1872 154,834
1855-59	54,493	1873 132,417
1860-64	41,665	1874 74,076
1865-69	107,672	1875 58,313
1870-74	108,675	1876 50,896
1875-77	49,786	1877 41,749

The following table, on the other hand, gives the number of emigrants from the German empire according to the official returns. The numbers are considerably lower than those of the last table. It will be seen that emigration has decreased greatly during recent years.

1873.....	103,438	German Emigrants.
1874.....	46,112	"
1875.....	30,773	"
1876.....	28,368	"
1877.....	21,964	"

Total..... 229,855 "

The greater part of the recent emigration has been from the maritime provinces. Out of 230,000 emigrants in the years 1873-77, 132,350 were from Prussia, Pomerania, Mecklenburg, Schleswig-Holstein, Hanover, Oldenburg, Bremen, and Hamburg. These states, with a total population (1875) of 9,245,000, accordingly lost 1½ per cent., the rest of the country (33,482,000 inhabitants) only 97,500, or 0.3 per cent. It must be added, however, that the emigration from South Germany was formerly much more considerable. Alsace-Lorraine lost only 1193 inhabitants in 1873-77 by emigration to America. The great mass of

German emigrants go to the United States,—90 5 per cent. of the whole (207,974) having embarked for that country in 1873-76. According to the official returns of the board of statistics at Washington, more than 2,900,000 immigrants arrived from Germany at American ports during 1820-1877. The rest of the emigrants find their way to Australasia, Brazil, the Cape, &c.

Immigrants and Foreigners.—In comparison with the emigrants, the number of immigrants is inconsiderable. The bulk come from Belgium, Holland, and Russia. The following table shows the number of natives of the empire who after being abroad have re-established themselves at home, and also the number of naturalized foreigners:—

	Re-established	Naturalized
1872	897	2296
1873	1284	2381
1874	1514	6532
1875	3735	9804
1876	2007	3643
1877	651	5310
Total	10,088	80,266

The number of foreign residents has considerably increased during 1871-75. In 1871 there were in the empire 40,852,037 natives and 206,755 foreigners; in 1875, 42,436,561 natives and 290,799 foreigners. The following table gives the native countries of the foreigners for 1871,—the latest date for which these statistics have been published:—

Austria-Hungary	75,702	Belgium	5,097
Switzerland	24,518	Luxembourg	4,828
Holland	22,042	France	4,671
Denmark	15,168	Italy	4,019
Russia	14,535	Turkey	504
Sweden and Norway	12,845	Spain	310
United States	10,698	Greece	192
Great Britain	10,104	Other countries	2,026

Density of Population.—The population is very unequally distributed, and the differences are far greater now than they were formerly. The mean density of the population had increased from about 120 inhabitants per square mile in 1820 to 150 in 1840, and to 205 in 1875. We have already pointed out the great increase of population during the present century in many agricultural provinces of Prussia. In South Germany, however, the density of population was considerable even at the beginning of the century. But Germany during this period has become an important industrial state, and, as in England, distinct industrial districts have been formed, where the inhabitants cluster in populous centres. Besides, the population of the cities has gone on increasing at the expense of the agricultural districts, so that the natural increase of the inhabitants

Classes of Towns	Number of Towns	Population.	Percent. of Total.
Large towns of more than 100,000 inhabitants	1871 8 1875 12	1,968,537 2,665,914	4.8 6.2
Middle-sized towns, from 20,000 to 100,000	1871 75 1875 88	3,147,272 3,487,357	7.7 8.2
Small towns, from 5000 to 20,000	1871 529 1875 592	4,588,364 5,132,971	11.1 12.0
Rural towns, from 2000 to 5000	1871 1716 1875 1686	5,086,625 4,922,781	12.4 11.5
Town population	1871 2328 1875 2328	14,790,798 16,209,528	36.1 37.9
Rural population	1871 .. 1875 ..	26,219,352 25,517,837	63.9 62.1

in these districts by the surplus of births is neutralized by the steady migration of the people into the cities. In

the accompanying official statistics all the inhabitants of communes with more than 2000 souls are designated "town population," and the term "rural population" is applied to those of the smaller places. But it must be remarked that in several provinces, such as Westphalia, Rhineland, and Oldenburg, there are many communes consisting of numerous small villages and hamlets which have not the character of a town, and the inhabitants of which are almost exclusively agriculturists. These rank as town population, which accordingly appears in the returns to be a little larger than it really is. The figures exhibit the extremely unequal increase of the different groups from 1871 to 1875.

Increase per cent. of Population, 1871-75.

Large towns	14.88
Middle-sized towns	12.41
Small towns	10.74
Rural towns	5.75
Town population	9.59
Rural population	0.79
Total for the empire	4.19

The following is a list of the 35 towns which had upwards of 50,000 inhabitants at the census of 1875. The first column exhibits the population within the boundaries of the municipal boroughs (Stadtgemeinde). The numbers in the second are not official, but include all suburbs of a really urban character. The latter therefore afford a better indication of the actual size of the several towns.

Population of the Principal Towns in 1875.

Towns	Within the Municipal Boundaries.	Within the Topographical Boundaries
1. Berlin	966,858	1,092,000
2. Hamburg	264,675	348,447
3. Breslau (Silesia)	239,050	289,080
4. Munich (Bavaria)	196,399	212,376
5. Dresden (Saxony)	197,265	197,265
6. { Elberfeld (Rhine)	80,539	{ 167,091
6. { Barmen	86,502	
7. Leipzig (Saxony)	127,387	160,688
8. Cologne (Rhine)	135,871	154,594
9. Frankfurt-on-Main (Hesse-Nassau)	103,138	134,776
10. Hanover	108,677	127,578
11. Magdeburg (Saxony)	87,625	122,739
12. Königsberg (East Prussia)	122,686	122,686
13. Bremen	102,632	111,039
14. Stuttgart (Württemberg)	107,273	105,092
15. Dantzig (West Prussia)	97,931	ab. 99,000
16. Nuremberg (Bavaria)	91,108	94,878
17. Strasburg (Alsace)	94,306	92,379
18. Chemnitz (Saxony)	78,209	85,334
19. Altona (Holstein)	84,037	84,037
20. Stettin (Pomerania)	80,372	80,372
21. Düsseldorf (Rhine)	80,695	80,695
22. Aix-la-Chapelle (Rhine)	79,606	79,606
23. Essen (Rhine)	54,790	76,450
24. Posen (Posen)	60,998	66,505
25. Brunswick	65,938	65,938
26. Mulhausen (Alsace)	58,463	65,881
27. Crefeld (Rhine)	60,905	62,905
28. Halle (Prov. Saxony)	60,503	60,503
29. Dortmund (Westphalia)	57,742	57,742
30. Augsburg (Bavaria)	57,213	57,213
31. Cassel (Hesse-Nassau)	58,043	56,745
32. Mainz (Hesse)	56,421	56,421
33. Potsdam (Brandenburg)	45,008	54,188
34. Metz (Lorraine)	45,856	53,151
35. Erfurt (Prov. Saxony)	48,080	50,477
Total	4,340,564	4,745,945

The inhabitants of these 35 towns amount to 10.1 or 11 per cent. of the entire population of the empire, according as we reckon by the municipal or the topographical boundaries. A similar proportion appears in France

Belgium; but the towns of England and Wales of 50,000 inhabitants and upwards have nearly 9½ million inhabitants, or 44 per cent. of the whole population.

Density of Population.—The town population amounts in some districts, such as Gumbinnen (East Prussia) and Lower Bavaria, to only 11 to 12 per cent., in others, as Zwickau, Leipzig, Düsseldorf, it reaches 50 to 66 per cent. Arranging Germany in 13 large divisions, we get the following table, the divisions being named after their principal provinces:—

Divisions.	Population 1875	Per Sq. Mile	Proportion per cent of	
			Town Popul	Rural Popul
1. Prussia (East and West) ..	3,199,171	129	29.8	70.2
2. Pomerania, Schleswig-Holstein, Mecklenburg, &c.	3,665,289	144	42.3	57.7
3. Brandenburg (not including Berlin) and Posen	2,765,687	142	30.0	70.0
4. Hanover, Münster, Oldenburg, &c.	2,437,476	137	36.0	64.0
5. Saxony (not including Palatinates) ..	4,381,136	138	29.0	71.0
6. Prer of Saxony, Anhalt, Brunswick, &c.	3,135,643	228	40.8	59.2
7. Silesia	3,843,699	247	33.0	67.0
8. Hesse, Hesse-Nassau, Minden, Lippe ..	3,073,566	250	33.6	66.4
9. Württemberg, Baden	3,445,180	226	39.0	61.0
10. Alsace-Lorraine, Palatinates	2,179,038	274	38.0	62.0
11. Rhineland, Ayrnberg	4,223,215	355	60.2	39.8
12. Saxony and Thuringia	3,630,972	305	40.8	59.2
13. Berlin	966,838	..	100	..
Total	42,377,500	206	37.0	63.0

The most thinly peopled territories are found, not as might be expected in the mountain regions, but in some parts of the plains. There are not more than 50 persons to the square mile (about the same proportion as in the Scotch Highlands) on the moors of the Isar north of Munich, on the East-Frisian moors, and on the Luneburg Heath. There are 50 to 100 inhabitants to the square mile on the Seenplatten of Pomerania and Mecklenburg, on the middle ridges of Schleswig-Holstein, in the northern districts of Hanover, in the Spreewald, &c. Leaving out of account the small centres, Germany may be roughly divided into two thinly and two densely peopled parts. In the former division has to be classed all the North German plain; there it is only in the valleys of the larger navigable rivers, and on the southern border of the plain, that the density reaches 150 to 200 inhabitants per square mile. In some places indeed it is far greater: at the mouths of the Elbe and the Weser, in East Holstein, in the delta of the Memel, 250 to 300, and in the environs of Hamburg even 400, inhabitants are found to the square mile. This region is bordered on the south by a very densely inhabited district, the northern boundary of which may be defined by a line from Breslau to Hanover, and its southern by a line from Coburg *via* Cassel to Münster. Here the density rises from 150 to 270 per square mile, for in this part of Germany there are not only very fertile districts, such as the "Goldene Aue" in Thuringia, but also centres of industry. The population is thickest in Upper Silesia around Beuthen (coal-fields), round Ratibor, Neisse, and Waldenburg (coal-fields), round Zittau (Saxony), in the Elbe valley around Dresden, in the districts of Zwickau and Leipzig as far as the Saale, in the Goldene Aue, on the northern slopes of the Hartz, and around Bielefeld in Westphalia. In all these places the density is greater than 350 inhabitants to the square mile, and in Saxony it exceeds 500. The third division of Germany comprises the basin of the Danube and Franconia (the Upper Main system), and sweeps to the north-west between the valleys of the Werra and the tributaries of the Rhine as far as Sauerland. The population of Franconia rises a little above that of the rest of this region, the density in the valley of the Regnitz between Nuremberg and Bamberg, and in the Main valley round Würzburg, reaching about 200 to 240 inhabitants per square mile. The fourth division embraces

the valleys of the Rhine and the Neckar. In the latter and in the Upper Rhine plain agriculture has reached a high degree of perfection, and the soil is so fertile as to support a population of 400 per square mile. North of the Niederrheinisches Schiefergebirge, again, are rich coal-fields,—making this the most important industrial district in Germany. Here indeed, in the governmental district of Düsseldorf, the population amounts to 700 per square mile,—about the same proportion as in the West Riding of Yorkshire; but no such density as exists in Lancashire (1500 to the square mile) is found anywhere in Germany. West of the Rhine a thickly peopled district is grouped round the coal-field of the Saar basin, but there is only a scattered population in the surrounding country. On the Elbe there are scarcely 100 inhabitants to the square mile.

Houses.—The number of houses was estimated in 1871 at 5,330,000, so that the average number of inhabitants per house is from 7 to 8. In England and Wales it is only 5.3 (1871). The greatest proportion of dwelling-houses to the population is in Alsace (5.1 persons to one house) and in Swabia (5.4). All the larger cities of Germany consist largely of houses in which a number of families live together. In Berlin the proportion per house is 5.7 persons, while in London it is only 5. This marks one important point of difference in the habits of the two countries.

Occupations.—The census of 1871 distinguishes 8 principal classes of occupation, but does not subdivide these. The official returns give for each class the number of persons engaged in the several occupations comprised in that class, with the number of attendants and other members of the families of those so occupied. The following table presents an abstract of the returns. In the case of Alsace-Lorraine the attendants are not given in the separate classes, but are all returned under class D.

Occupations.	Engaged in the several occupations	Attendants and other members of families.	Total.
A. Agricultural class	2,908,798 females 976,669	2,066,656 2,217,311	12,170,307
B. Industrial class	4,468,780 females 1,086,071	2,462,937 2,360,060	12,407,720
C. Commercial class	1,022,266 females 201,611	822,240 1,700,435	3,265,006
D. Domestic class (and general labourers) ..	1,777,116 females 595,001	2,344,335 4,711,494	6,660,638
E. Army and Navy	690,800 females 20,051	508,413 50,051	508,413
G. Other occupations ..	606,781 females 98,974	318,208 824,000	1,731,970
H. Persons not returned under any occupation ..	411,384 females 620,481	266,322 604,085	1,086,109
I. Not stated (poor, &c.)	437,008
Total	15,540,610	25,080,214	41,068,792

This table does not admit of comparison with the census returns of England and Wales, the mode of classification being different. It will be seen that more persons belong to the industrial than to the agricultural class.

INDUSTRIES.

Some account of different industries has already been given in connexion with the productions of the empire. The principal textile manufactures have still to be noticed.

Cotton Manufacture.—Before 1871 the production of cotton fabrics in France exceeded that in Germany; but as the cotton manufacture is pursued largely in Alsace, more than 2 million spindles being employed there, the balance is now against the former country. In 1873 there were about 5 million spindles in Germany and 4,611,000 in France. From the subjoined table of imports and exports (gross

weight, the net weight being about 4 per cent. less) of the raw material, it will be seen that this industry has not improved since 1873—

	Total Imports of Raw Cotton	Total Exports of Raw Cotton	Excess of Imports
	Cwts	Cwts	Cwts
1873	3,609,000	1,153,000	2,456,000
1874	3,490,000	818,000	2,672,000
1875	3,199,000	819,000	2,380,000
1876	3,513,000	705,000	2,813,000
1877	3,262,000	831,000	2,431,000
1878	3,289,000	973,000	2,313,000

Cotton spinning and weaving are not confined to one district, but are prosecuted in Upper Alsace (Mulhausen, Gebweiler, Colmar), in Saxony (Zwickau, Chemnitz, Annaberg), in Silesia (Breslau, Liegnitz), in the Rhine province (Dusseldorf, Munster, Cologne), in Erfurt and Hanover, in Wurtemberg (Reutlingen, Cannstadt), in Baden, Bavaria (Augsburg, Bamberg, Baireuth), and in the Palatinate. The number of hands occupied in the mills in 1875 was 68,555 (34,385 males, 34,170 females) and in the weaving establishments 186,496 (124,732 males and 61,764 females). Of these 98,188 were in Saxony. The production of cotton yarn is not sufficient for the home demand, and for some years back the imports of the article have exceeded the exports by about 200,000 cwts., till 1878, when the excess was only 117,000 cwts.

Woolen and Worsted.—In this class of manufactures Germany is far behind France. First of all, the home production of wool is not sufficient. In 1873–75 the imports of wool exceeded the exports by 300,000 cwts. per annum, and in 1876–78 the excess amounted to 800,000 cwts. In 1875 there were about 1,200,000 spindles for carded woollen yarn,—about 700,000 of them in Prussia, and 320,000 in Saxony. For worsted spinning there were 450,000 spindles,—Upper Alsace having 180,000, and Saxony 110,000; nevertheless the production falls short of the demand, and from 150,000 to 250,000 cwts. must be obtained from foreign countries. The manufacture of woollen cloth is well developed, and is prosecuted for exportation. The cloth is valued as being well woven, durable, and cheap. The centres of its manufacture are the Rhine province, Brandenburg, Lower Silesia, Magdeburg, Thuringia, Saxony, Wurtemberg, and Alsace. In 1875 there were altogether 192,452 persons engaged in the woollen industry.

Linen, Hemp, and Jute.—Germany, although linen was formerly one of her most important articles of manufacture, is now left far behind in this industry, not only by Great Britain and France, but also by Austria-Hungary. In 1874 there were 326,538 spindles at work in Germany for flax, hemp, and jute spinning, while there were 415,000 in Austria, 663,000 in France, and 1,670,000 in Great Britain. About 300,000 cwts. of linen yarn are imported into Germany annually, whereas Austria exports about 100,000 cwts. Hand-loom weaving is practised all over Germany, but centres principally in Saxony, Silesia, and Westphalia. In recent times also power-loom weaving has been extending. In 1873 there were 68 establishments in Germany, principally at Elberfeld and Barmen, with 3473 power-looms, including 7 factories, with 846 power-looms, for jute. The linen industry employed 187,793 persons in 1875. The demand for linen is nearly covered by the home production.

Silk.—Raw silk can scarcely be ranked among the products of the empire, and the annual demand has thus to be provided for by importation. It amounts to about 50,000 cwts., there being some superior silk-weaving establishments. The main centre of the silk industry is Orefeld and its neighbourhood; then come Elberfeld and Barmen, Aix-la-Chapelle, as well as Berlin, Potsdam, Chemnitz and

Annaberg, Munich, Stuttgart, Saargemünd, &c. The exports of silk stuffs always exceed the imports.

General Census of Industries.—In 1875 a census of industrial occupations was taken in Germany. The following table gives the numbers of the different establishments and of the persons engaged in them:—

Classes.	Establishments.	Persons Engaged
1. Horticulturists	13,072	24,893
2. Fishermen	15,686	19,623
3. Miners	7,893	433,109
4. Workers in stone, clay, glass	51,235	265,139
5. Workers in metal	164,328	420,445
6. Workers in machines, instruments, &c	88,635	307,705

Total	2,938,572	6,467,570

ROADS, RAILWAYS, AND CANALS.

Roads.—The construction of good highways has been well attended to in Germany only since the Napoleonic wars. The separation of the empire into small states was favourable to road-making, inasmuch as it was principally the smaller Governments that expended large sums for their network of roads. Thirty years ago the best roads were found in Hanover and Thuringia: the Thuringer Wald has been almost transformed into a park by its splendid roads. But some districts suffer even still from the want of good highways. The introduction of railways for a time diverted attention from road-making, but this neglect has of late been to some extent remedied. In Prussia the circles (*Kreise*) have now themselves undertaken the charge of the construction of the roads; but they receive a subsidy from the public funds of the several provinces. The total length of the public roads is now estimated at 72,000 miles.

Railways.—The period of railway construction was inaugurated in Germany by the opening of the line from Nuremberg to Fürth in 1835, but the development of the system was slow. The want of a central government operated injuriously here, for it frequently happened that intricate negotiations and solemn treaties between several sovereign states were required before a line could be constructed; and moreover the course it was to take was often determined less by the general exigencies of commerce than by many trifling interests or desires of neighbouring states. The state which was most self-seeking in its railway politics was Hanover, which separated the eastern and western parts of the kingdom of Prussia. The difficulties arising to Prussia from this source were experienced in a still greater degree by the seaports of Bremen and Hamburg. Until 1866 there was no railway from Bremen into the interior of Germany, while now there are four. Prior to 1866 the construction of railways advanced pretty uniformly, the average construction during the years from 1840 to 1865 having been from 340 to 370 miles per annum. Germany was at that time far outstripped in the extent of its railway system by England, Belgium, and Switzerland, and even by France. A new period of railway construction begins

with the year 1866, and is closely connected with the economical and political progress of Germany. Numerous great undertakings were then set on foot, partly to remedy the defects of the existing system. Everywhere it became a primary object to establish the most direct lines of communication between important places of industry and commerce. As a consequence the German railway system was immensely enlarged, and from 1865-75 it has nearly been doubled. In 1872, 2000 miles were opened, the average from 1869 to 1877 being 1080 miles annually, so that Germany now owns a greater length of railways than any other state in Europe. On the 31st December 1877 Germany had 18,830 miles, Great Britain and Ireland 17,092, France 14,785. As regards proportion to the area and population, however, Belgium, Great Britain, and Switzerland are still in advance. In 1877 Belgium had 320 miles of railways to every 1000 square miles, Great Britain 273, Switzerland 155, and Germany 147. The following table exhibits the development of the German railways, including those of Alsace-Lorraine:—

Years Dec 31	Length of Lines open for Traffic	Of which double Lines	Cost of Construction
	Miles	Miles.	£
1840	304		
1850	3,753		
1860	7,195		
1865	8,387		
1870	11,457	3,699	207,608,000
1875	17,061	5,622	339,325,000
1876	18,080	5,785	378,558,000
1877	18,830		

In recent years the multiplication of competing railways has greatly reduced the receipts of the older lines. The total amount of capital sunk in railway construction is estimated for the year 1876 at £373,558,000, or just about half the capital invested for the same purpose in Great Britain (£741,800,000). From the subjoined table it will be seen that the working expenses have considerably advanced during late years, and dividends accordingly have experienced a great decline. Railways formerly paying 15 to 18 per cent. have gone down to 5 to 6, the average dividend, which in 1870 was still 6 per cent., in 1876 had fallen to 4·4 per cent.

	Total Receipts	Total Working Expenditure.	Net Receipts	Proportion of Expenditure to total Receipts
	£	£	£	Per cent.
1870	25,312,000	12,770,000	12,543,000	50·5
1875	42,151,000	26,594,000	15,617,000	63·0
1876	42,892,000	28,558,000	16,908,000	62·0

The making of railways has from the outset been regarded by some German states as exclusively a function of the Government. The South German states, for example, possess only state railways. In Prussia numerous companies have in the first instance constructed their systems, and the state has contented itself for the most part with laying lines in such districts only as were not likely to attract private capital. Yet, in order to establish a preponderating influence over the administration of all German railways, the Government has for some time been buying up private lines. Saxony not long ago purchased all the Saxon railways belonging to private companies. The following table gives the proportion of state and private railways at 31st December 1877, the minor North German states being classed along with Prussia. Of these Oldenburg alone possesses a greater length of railways belonging to the state than of those in the hands of private companies. The railways of Alsace-Lorraine are the

property of the empire. The number of independent managements in 1878 was 67.

States	State Railways	Private Railways worked by State	Private Railways.	Total
	Miles	Miles.	Miles	Miles
Prussia and minor German States . . .	3,285	2,060	6,857	12,202
Bavaria	2,241	169	371	2,781
Saxony	1,035	23	170	1,228
Württemberg	761		10	771
Baden	651	77	4	732
Hesse	179		270	449
Alsace-Lorraine	600		7	607
Total	8,512	2,329	7,689	18,830

Canals.—Germany cannot be said to be rich in canals. In South Germany the Ludwigs-canal was until the annexation of Alsace-Lorraine the only one of importance. It was constructed by King Ludwig of Bavaria in order to unite the German Ocean and the Black Sea, and extends from the Main at Bamberg to Kelheim on the Danube. Alsace-Lorraine had canals for connecting the Rhine with the Rhone and the Marne; the coals of the Saar valley were conveyed by canals to Lorraine. The North German plain has several canals, of which only the more important need be named. In the east a canal by which Russian grain is conveyed to Königsberg joins the Pregel to the Memel. The Netze canal unites the Vistula and Oder. The Upper Silesian coal-field is in communication with the Oder by means of a canal. The greatest number of canals is found around Berlin; they serve to join the Spree to the Oder and Elbe. Smaller canals are found also in the north-west. The Mosse and the Rhine are also connected by a canal. The 70 canals in Germany have a total length of only 1250 miles, a very small extent when the other canal systems of western Europe are compared with it.

POSTS AND TELEGRAPHS.

With the exception of Bavaria and Württemberg, which have administrations of their own, all the German states belong to the system of the reichspost. Since 1874 the postal and telegraphic departments have been combined. Both branches of administration have undergone a surprising development during the last 10 years, especially since the reduction of the postal rates. Germany, including Bavaria and Württemberg, constitutes with Austria-Hungary a special postal union (Deutsch-Oesterreichischer Postverband), besides forming part of the international postal union. There are no statistics of posts and telegraphs before 1867, for it was only when the North German union was formed that the lesser states resigned their right of carrying mails in favour of the central authority. Formerly the prince of Thurn-and-Taxis was postmaster-general of Germany, but only some of the central states belonged to his postal territory. The seat of management was Frankfurt. Of late years the number of post-offices has increased considerably, as will be seen from the following figures, in which the statistics of the Bavarian and Württemberg post-offices are included, as well as those of the reichspost. In 1872 there were 7400 post-offices; in 1877, 8600. In the latter year therefore there was one post-office for every 23 square miles. In 1877 there were 3194 imperial post-and-telegraph offices, and 3746 imperial post-offices, while the Bavarian post-offices numbered 1243, and those of Württemberg 499. The following table shows the increase of letter circulation from 1872 to 1877:—

	Letters Imperial Post	Total in German Empire	Average Number to each Person
	Millions	Millions	
1872	362 0	407 8	10
1873	429 0	492 4	12
1874	466 6	521 9	13
1875	498 2	576 0	14
1876	516 4	596 8	14
1877	521 5	604 2	14

The average number of letters to each person is thus a little greater in Germany than it is in Ireland, whereas it is 26 in Scotland and 35 in England. The number of post-cards has increased from 26·5 millions in 1872 to 99·3 millions in 1877. The following table shows the general postal circulation during the three years 1875-77.—

	1875	1876	1877.
	Millions	Millions	Millions
Letters	576 0	596 3	604 2
Post-cards	64 7	82 7	98 3
Printed papers	33 0	101 0	112 4
Newspapers	362 8	414 2	433 5
Samples	0 3	9 0	9 8
Money orders	33 5	39 3	...
Total amount of money orders and remittances	£840	£793	£781
Parcels	73 4	80 3	82 3
Total weight of parcels . . .	1b 559	1b 583	1b 915

Telegraphs.—By combining the postal and telegraphic departments Germany has been saved a large number of officials; but great sums are still spent annually on the extension of the telegraph system. Since 1876 important localities have been brought into communication with Berlin by subterranean wires. This plan is expensive, but under it a considerable saving is anticipated in repairs. The number of telegraph offices in 1877 was 7251, of which about 4600 belonged to the state, and the rest to private railways. The following table shows the progress of the telegraphic system between 1872 and 1877, and the number of messages in these two years:—

Telegraph Service.	1872.	1877.
	Miles.	Miles
Length of line	23,850	33,660
Length of wire	77,870	121,810
Number of offices	4,038	7,251
Number of messages—		
Home service	8,478,000	8,994,000
International (includ. in transit)	4,946,000	5,208,000

The increase of messages is insignificant, a circumstance which must be attributed to the recent dulness of trade. On the whole the telegraph is not as yet used to a very great extent in Germany. The number of messages for every 100 inhabitants in 1877 was 33, as compared with 47 in Norway, 49 in Denmark, 54 in Belgium, 58 in the Netherlands, 64 in Great Britain, and 100 in Switzerland.

SHIPPING.

The German mercantile marine has always been distinguished by the excellence of its personnel. The seamen of Frisia are acknowledged to be among the best in the world, and the shipping of Bremen and Hamburg had won an everywhere respected name long before a German mercantile marine, properly so-called, was heard of. Many Hamburg vessels sailed under charter of English and other houses in foreign waters, especially in the Chinese. Since 1868 all German ships have carried a common flag—black, white, red—but formerly Oldenburg, Hanover, Bremen, Hamburg, Lübeck, Mecklenburg, and Prussia had each its

own flag, and Schleswig-Holstein vessels sailed under the Danish flag. It is but lately that a uniform mode of measuring the hold tonnage of German ships has been introduced, and accordingly it is only since 1871 that it has been possible to give an exact statement of the position of German shipping. The official returns show that the marine is on the increase. The following table gives its position on the 1st of January in the years 1872-78. The tonnage is reckoned according to the English register ton.

	Sailing Vessels		Steamers		Total	
	Number	Tons	Number	Tons	Number	Tons.
1872	4,354	892,000	175	97,000	4,529	988,000
1873	4,811	869,000	218	130,000	4,927	999,000
1874	4,343	806,000	253	168,000	4,495	1,084,000
1875	4,303	878,000	299	190,000	4,602	1,068,000
1876	4,426	901,000	319	184,000	4,745	1,084,000
1877	4,491	923,000	318	181,000	4,809	1,104,000
1878	4,469	935,000	336	188,000	4,805	1,118,000

The lowest tonnage of vessels included in this return is 16 tons for sailing vessels and 11 tons for steamers. On comparing the state of the German marine with that of other countries we find that Germany ranks fourth in the list of maritime nations. Great Britain and the United States have considerably larger fleets. That of Norway also was even in 1871 greater than that of Germany, and it has increased much more rapidly than the other since that time; but on the other hand the mercantile marines of France and Italy, which in 1871 were larger than the German, are both now less. The following table shows the proportion of the mercantile shipping of Germany belonging to each of the maritime states on the 1st of January 1878. It must be borne in mind that Bremen and Hamburg properly consist only of one port each, whereas Prussia has hundreds of miles of coast-line both on the North Sea and on the Baltic.

States.	Number of Ports.	Sailing Vessels	Steamers.	Total.
		Tons.	Tons.	Tons.
Prussia	243	464,477	31,573	496,050
Hamburg	2	137,347	84,127	221,474
Bremen	2	158,677	57,377	216,054
Mecklenburg	2	108,621	3,812	112,383
Oldenburg	21	61,774	27	61,801
Lübeck	1	8,760	0,463	10,223
Total	271	934,550	183,379	1,117,929
North Sea Ports.	62	419,098	98,669	458,397
Baltic Ports	209	514,552	144,660	659,538

The number and the tonnage of steamers have, as in other countries, increased greatly, while those of sailing vessels have remained almost stationary. The aggregate horsepower of the steamers in 1871 was 23,287; in 1877 it was 50,603. The number of seamen employed in 1878 was 40,832, and of those 8173 served on board steamers.

In 1876 165 sailing vessels of 35,439 tons, and 14 steamers of 6200 tons, were built in Germany; and 8 sailing vessels of 3862 tons, and 1 steamer of 1910 tons, were built abroad. There were besides 50 ships with a total tonnage of 21,755 which had been bought in America, Holland, and Great Britain.

The shipping returns of German ports have lately fluctuated but little. The total amount was 13,311,000 tons in 1876. A striking difference will be observed in the following table in the returns between the numbers entering and clearing in ballast:—

Total Tonnage of Ships, 1876.

	With Cargo	In Ballast	Not for Trade	Total
Entered	Tons. 6,072,000	Tons 505,000	Tons 130,000	Tons 6,585,000
Cleared ..	4,100,000	2,619,000	128,000	6,726,000

Only 44 per cent. of the ships that trade with German ports sail under the German flag. British ships have a very considerable trade in German ports. They constitute 32 per cent. of the total tonnage, and as much as 47 per cent. of the tonnage of steam vessels. Denmark follows next with 7·2 per cent., Sweden 4·8, Norway 4·6, Russia 2·3, Holland 2·1, France 1·2, United States 1·2, Italy 0·5, other countries 0·4. The number of voyages in all made by German ships in 1876 was 45,492, of which 12,963 were made between German ports. Much more considerable, however, is the trade of German ships between the home ports and foreign countries, as the subjoined table will show, while no fewer than 9777 voyages were made in 1876 by German vessels without calling at any home port:—

	Number of Ships with Cargo	Tonnage of Ships with Cargo.	Number of Ships in Ballast	Tonnage of Ships in Ballast.
Home trade (average of entered and cleared ships)	12,963	677,000	5,194	220,000
Foreign (said into German ports)	8,002	1,084,000	710	79,000
trade (cleared from)	5,410	1,552,000	3,397	602,000
Voyages of German ships be- tween foreign ports	6,900	3,214,000	2,827	880,000
Total	33,364	7,129,000	12,128	1,782,000

There were 5544 voyages made between non-German ports in Europe, the greater number being between one English port and another. Many German vessels also run between the Baltic ports of Russia and Sweden. From European ports 993 vessels sailed for non-European ports, and 869 returned thence to Europe. Here also the greater number ran from Great Britain to the United States, the West Indies, and South America. 2371 ships made their voyages without touching at European ports. Most of these were engaged in the coasting trade in the Chinese Seas, on the South American coasts, and in the West Indies.

As regards the shipping of the most important German ports, the following table will show the total tonnage of ships entered and cleared in 1876:—

Ports.	Tonnage.	Ports.	Tonnage.
Hamburg	4,408,000	Kiel	608,000
Bremerhafen .. .	1,800,000	Pilau	440,000
Stettin	1,144,000	Königsberg	418,000
Naufahrwasser (Danzig) .. . }	780,000	Geestemünde	378,000
Lübeck	648,000	Möml	352,000
		Swinemünde	332,000

COMMERCE.

Statistics relating to the foreign trade of the empire are necessarily confined to very recent times. The quantities of such imported articles as are liable to duty have indeed been known for many years; and some years ago an attempt was also made to compile official tables showing the value both of imports and of exports. But when the results of these tables proved the importation to be very much greater than the exportation, the conviction arose that the valuation of the exports was erroneous, and below the reality. There is no compulsory declaration of such goods, and consequently the attempt to compute statistics of this nature has been abandoned since 1875. It must at the outset be observed that the customs frontier does not coincide with the political frontier of Germany, for it does not take in the free-port territories of Hamburg and Cuxhaven, Bremen,

Bremerhafen and Geestemünde, &c. (in all, 129 square miles with 593,040 inhabitants, in 1875), besides some communes in Baden adjoining the Lake of Constance (22 square miles, 5236 inhabitants). On the other hand the grand-duchy of Luxembourg (998 square miles, with 205,158 inhabitants in 1875) and the small Austrian commune of Jungholz 206 inhabitants), near Füssen, belong to the German Zollverein. The collection of duties is a function of the empire. The following table shows the results of the official calculations of the imports into Germany for 1872-76, and also the values of the exports, but in the case of these it is only the figures for the years 1872-74 that are official. The numbers for 1875 and 1876 are those published by Professor Laspeyres in the *Économiste Français*.

Years	Imports	Exports	Transit
1872	£173,400,000	£124,700,000	£54,700,000
1873	212,800,000	124,400,000	61,700,000
1874	183,700,000	121,600,000	
1875	176,500,000	127,400,000	
1876	190,200,000	127,000,000	
Average ..	187,100,000	125,200,000	

The extremely slight variation which this table shows in the exports of the several years from 1872 to 1876 appears so improbable that we can hardly venture to make it a basis of calculation, or to draw a conclusion so unfavourable to the trading balance of Germany as the figures would suggest. The proportion per head of population is, as regards imports and exports respectively, about £4, 10s. and £3, whereas the proportion in Great Britain in 1876 amounted in the one case to £11, 10s. and in the other to £6, thus showing the German trade to be less than half that of England. The statistical tables do not specify the several foreign markets for imports and exports; they only give the value of imports on the different frontiers.

Frontiers.	Total Value of Imports.	
	1875.	1876.
	Millions.	Millions.
North Sea line, including Bremen and Hamburg	£56·6	£62·4
Denmark	1·0	1·0
Russia	19·0	10·2
Austria	32·2	30·3
Switzerland	8·0	0·2
France	11·3	12·1
Belgium	10·3	18·3
Holland	27·1	28·8
By post, or frontier not stated	5·0	4·0
Total	176·5	190·2

According to the official trade returns of Great Britain, France, and other countries, the trade between Germany and these countries is very considerable. By the English tables the importation from Germany to British ports was in 1875-76 between £21,000,000 and £22,000,000; the exportation to Germany in 1875 was £23,300,000, and in 1876, £30,100,000. The movement of trade is shown in the following tables of the principal articles imported and exported. We begin with articles of consumption:—

Articles.	1872.		1877.	
	Imports.	Exports.	Imports.	Exports.
Animals, except horses..No	1,400,000	1,719,000	2,448,000	1,848,000
Grain and Flour	28,000,000	21,800,000	78,070,000	20,600,000
Herring	69,000	...	667,000	...
Coffee	1,855,000	...	1,918,000	...
Sugar	870,000	284,000	155,000	1,852,000
Wine	817,000	400,000	1,159,000	380,000
Beer	100,000	280,000	600,000	1,380,000
Wool	23,000	142,000	58,000	162,000
Tobacco	1,138,000	140,500	1,048,000	120,000

The weights are stated in hundredweights (cwt.) net throughout (see *Statistical Abstract* published by the English Board of Trade, No. V., 1878). This table shows that of late years Germany has had to order considerable quantities of grain from abroad. The value of the importation, estimated at £14,000,000 in 1872, was nearly £36,000,000 in 1877. Similarly the value of the imported animals advanced from £4,400,000 in 1872 to £9,500,000 in 1877.

The following table gives the imports and exports of the principal raw materials:—

Articles	1872		1877	
	Imports	Exports	Imports	Exports
Coal, lignite, &c. Cwts.	71,000,000	76,355,000	85,000,000	100,181,000
Iron, pigs	8,200,000	5,000,000	6,855,000	16,110,000
Lead, pig	12,262,000	3,016,000	10,550,000	9,110,000
Cotton, raw	163,000	148,000	60,000	619,000
Cotton, raw	2,830,000	611,000	3,120,000	708,000
Flax	780,000	667,000	1,580,000	1,010,000
Hemp	500,000	218,000	930,000	499,000
Wool, raw	1,070,000	337,000	1,370,000	415,000
Silk, raw cocoons	61,300	16,000	63,000	30,000
India	1,181,000	290,000	857,000	208,000
Opium	1,100,000	790,000	2,410,000	327,000
Lamseed, &c.	1,110,000	670,000	1,110,000	1,351,000

With regard to the proper products of industry, the exports, with few exceptions, such as yarn, exceed the imports in every case, as is shown in the table below. The total value of all fabrics imported is estimated at about £30,000,000, that of those exported at from £42,000,000 to £45,000,000. But, even supposing the last figures to be too low, the difference between the German and the British trade is still very great, since the value of all the industrial products exported by Great Britain may be stated at £170,000,000 for the year 1875 (see *Almanach de Gotha*, 1877). The difference is greatest in the textile industries,—the value of tissues exported from England in 1875 being estimated at £100,000,000, while that of Germany did not rank higher than from £20,000,000 to £25,000,000. Articles of hardware are showing a great decrease of imports and a considerable increase of exports.

Industrial Products—Imports and Exports.

The principal ports of import and export are Hamburg and Bremen, and in these places the annual amount of shipping business has advanced step by step with the general development of German trade. As to the total value of goods entering Hamburg we have accurate statistics for several decades.

Imports of Hamburg.

Average.	Total Imports, exclud. Bullion.		Total Imports, exclud. Bullion.	
	Millions.	1873	Millions.	1873
1840-50	£20.5	1873	£26.3	—
1851-60	23.5	1874	24.3	—
1861-70	49.8	1875	85.1	—
1871	77.3	1876	85.2	—
1872	85.6	1877	88.8	—

The stagnation in the development of trade during the period 1871-77 is obvious; and with Bremen the case is the same. The following table states the total imports of Bremen by sea and from the interior. The importation from Germany or the Zollverein territory represents about one-third of the total amount. Bremen trades principally with the United States; Hamburg more with England, South America, &c.

GOVERNMENT.

The German empire is a union of 25 sovereign states, —4 kingdoms, 6 grand-duchies, 5 duchies, 7 principalities, 3 free towns. Alsace-Lorraine, ceded by France at the peace concluded 10th May 1871, forms a twenty-sixth constituent of the confederation, but it is administered by the central authority. The supreme direction of the military and political affairs of the empire has, by the vote of the reichstag or diet of the North German confederation, been vested in the king of Prussia, who accordingly bears the title of German Emperor (Deutscher Kaiser).

The imperial dignity is hereditary in the line of Hohenzollern, and follows the law of primogeniture. The emperor exercises the imperial power in the name of the confederated states. In his office he is assisted by a federal council or bundesrath, which represents the Governments of the individual states of Germany. The members of this council, 59 in number, are appointed for each session by the Governments of the individual states. The legislative functions of the empire are vested in the emperor, the bundesrath, and the reichstag or diet. The members of the latter, 397 in number, are elected for a space of three years by universal suffrage. Vote is by ballot, and one member is elected by (approximately) every 100,000 inhabitants.

As regards its legislative functions, the empire has supreme and independent control in matters relating to military affairs and the navy, to the imperial finances, to German commerce, to posts and telegraphs, and also to railways, in so far as these affect the common defence of the country. Bavaria and Württemberg, however, have preserved their own postal and telegraphic administration. The legislative power of the empire also takes precedence of that of the separate states in the regulation of matters affecting freedom of migration (Freizügigkeit), domicile, settlement, and the rights of German subjects generally, as well as in all that relates to banking, patents, protection of intellectual property, navigation of rivers and canals, civil and criminal legislation, judicial procedure, sanitary police, and control of the press and of associations.

The executive power is in the emperor's hands. He represents the empire internationally, and can declare war if defensive, and make peace as well as enter into treaties with other nations; he also appoints and receives ambassadors. For declaring offensive war the consent of the federal council must be obtained. The separate states have the privilege of sending ambassadors to the other courts; but all consuls abroad are officials of the empire, and are named by the emperor.

Both the federal council and the reichstag meet in annual sessions convoked by the emperor who has the right of proroguing and dissolving the diet; but the prorogation

must not exceed 60 days, and in case of dissolution new elections must be ordered within 60 days, and the new session opened within 90 days. All laws for the regulation of the empire must, in order to pass, receive the votes of an absolute majority of the federal council and the reichstag. The subjoined table gives the number of votes which the separate states have in the federal council. Each state may appoint as many members to the federal council as it has votes. The table also gives the number of the deputies in the reichstag. The official order of precedence of the 26 states is given in a former table (see p. 155); here they are arranged in the order of the number of their inhabitants.

Representation in Federal Council and Reichstag.

States of the Empire in order of their Population	Population, 1875	Votes in the Federal Council.	Deputies in the Reichstag

The federal council is presided over by the chancellor of the empire (Reichskanzler). Imperial measures, after passing the federal council and the reichstag, must obtain the sanction of the emperor in order to become law, and must be countersigned, when promulgated, by the chancellor of the empire. All members of the federal council are entitled to be present at the deliberations of the reichstag. The federal council, acting under the direction of the chancellor of the empire, is also a supreme administrative and consultative board, and as such it has nine standing committees, viz.:—for army and fortresses; for naval purposes; for tariffs, excise, and taxes; for trade and commerce; for railways, posts, and telegraphs; for civil and criminal law; for financial accounts, for foreign affairs; and for Alsace-Lorraine. Each committee includes representatives of at least four states of the empire.

For the several branches of administration a considerable number of imperial offices have been gradually created. All of them, however, either are under the immediate authority of the chancellor of the empire, or are separately managed under his responsibility. The most important are the chancery office, the foreign office, and the general post and telegraph office. But the heads of these do not form a cabinet.

By the electoral law of 31st May 1869 every German of twenty-one years of age is entitled to be an elector, and every one who has completed his twenty-fifth year,

and has resided for a year in one of the federal states, is eligible for election. The deputies are unsalaried, but during the session they have the right of travelling free by rail. The following table shows the political composition of the reichstag after the four elections from 1871 to 1878 —

Parties.	1871	1874	1877	1878.

All the German states are constitutional, except Alsace-Lorraine and the two grand-duchies of Mecklenburg. The six larger states have adopted the two-chamber system, but in the composition of the houses great differences are found. The following table gives analyses of the membership for the sessions of 1878. As regards the lower house, 60,000 inhabitants elect one deputy in Prussia, 33,000 in Bavaria, 35,000 in Saxony, 20,000 in Württemberg, 24,000 in Baden, 18,000 in Hesse.

	Prussia	Bavaria	Saxony	Württemberg	Baden	Hesse

Higher clergy	1
Universities
Total for Lower Houses	434	156	80	53	63	60

The lesser states also have chambers of representatives numbering from 12 members (in Hesse) to 46 members (in Brunswick), and in most states the different classes, as well as the cities and the rural districts, are separately represented. The free towns have legislative assemblies, numbering from 120 to 200 members. In the so-called landtagen (diets) of Mecklenburg, which have but few privileges, 684 rittegitiger (allodial estates) are represented and only 40 towns.

FINANCE.

The most important expenses which the budget of the German empire has annually to meet are those of the central administration, the army and navy, posts and telegraphs, the high court of justice, the foreign office, and some smaller items. For defraying these, all customs receipts and the net amount of certain excise duties are paid into

the imperial treasury (reichskasse). Of the excise duties those on beet-root sugar, salt, and tobacco are common to all the states; but the imperial malt tax is not imposed in Bavaria, Württemberg, Baden, or Alsace-Lorraine. The three first-named states are likewise exempt from the imperial excise on spirits. Additional receipts are derived from the duty on bill stamps, from posts and telegraphs (excluding Bavaria and Württemberg), from the railways in Alsace-Lorraine, &c. These receipts are, however, insufficient to meet the expenses of the administration, and for that reason the separate states have to make contributions to the revenues of the empire, varying in proportion to their population. Bavaria, Baden, Württemberg, and Alsace-Lorraine pay proportionally higher direct contributions, because they impose taxes on their own account on malt and spirits; so also do Bremen and Hamburg, because they are situated outside the customs territory. For the last few years the average contributions have ranged from £3,000,000 to £4,000,000, but they are increasing with the diminution of the funds available from the French war indemnity. These contributions press heavily upon the minor states.

The imperial budget is voted every year by the reichstag. The ordinary and extraordinary expenses for the financial year ending March 31, 1879, were distributed as follows —

Expenditure, 1878-79.

	Ordinary	Extraordinary
Imperial chancery	£223,799	£116,516
Reichstag	6,100	1,500
Foreign office	305,233	26,350
Army	16,125,914	1,583,927
Navy	1,805,520	1,729,008
Invalid fund	1,609,658	...
Military pensions	829,073	...
Civil pensions	48,556	...
Imperial judiciary	40,300	1,750
Imperial court of railway affairs	13,637	505,117
Posts and telegraphs	664,967
Imperial audit	22,526	500
Interest of debt of the empire	339,075	...
Mintage of imperial coins	1,135,000
Expenditure in remission of war-laxes	496,766
Total	20,775,438	6,040,402

Revenue, 1878-79.

1. Customs, net	£5,327,524
2. Excise, net	6,861,768
Common duties. { Beet-root sugar	£2,368,935
Salt	1,099,000
Tobacco	47,070
Spirits	20,400

3. Contributions by territories outside the Zollverein	237,000
4. Stamps	332,655
5. Posts and telegraphs (gross revenue £3,443,000), net	764,420
6. Railways in Alsace-Lorraine (gross £1,903,600), net	567,300
7. Imperial printing-office, net	8,716
8. Imperial bank (share of profits)	100,500
9. Various revenues	381,569
10. Invalid fund	1,002,658
11. Interest of imperial funds	366,210
Total direct revenue	16,640,810

Extraordinary supply (loans, various funds)	5,826,753
Contributions of states to revenue	4,567,276
Total revenue to cover expenditure	26,824,840

The direct contributions of the principal states of the empire to the revenue for 1878-79 were as follows:—

Prussia	£2,074,730	Saxony	£228,736
Bavaria	954,137	Alsace-Lorraine	103,020
Württemberg	340,380	Hesse	71,125
Baden	241,525	Mecklenburg	40,602

Customs Revenue.—The revenue from the customs duties has increased but little since 1872. In that year it was £5,534,000, and in 1873, £6,131,000; but in 1877-78 it

was only £5,768,000. No export duties have been raised in Germany for many years. On the other hand, all imported goods were taxed till 1865, with very few exceptions. Since then free trade has been more in favour, and a considerable reduction has taken place in the number of taxed articles. There are still, however, according to the official lists, about 148 articles on which custom duties are levied under 43 divisions. Raw materials are duty free. Four-fifths of the receipts (£4,323,000) are derived from articles of consumption, coffee being the principal item, after which come tobacco, wine, spirits, &c. The subjoined table shows the customs receipts, in round numbers, from the following items in 1878:—

Coffee	£1,838,000	Herrings	£108,000
Tobacco	321,000	Pork	103,000
Wine and spirits	517,000	Sugar and molasses	101,000
Salt	250,000	Rice	83,000
Fruit	258,000	Miscellaneous	235,000

The preceding table shows great differences when compared with the corresponding list for Britain. The consumption of coffee is considerably larger,—Germany having imported 2,128,000 cwts. in 1876, Great Britain only 1,361,000. The duty is at the same time much higher than in England, where the revenue from coffee was only £200,000. On the other hand, tea yields only £36,000 duty in Germany, but in England £3,700,000; wine and spirits in Germany £517,000, in England £7,500,000; tobacco, in Germany £821,000, in England £7,800,000.

The German customs tariff serves as a protective duty for several industrial products, although in general a free-trade policy has prevailed in Germany during the last ten years. In 1873 the duties on iron were abolished; still its importation, owing to the stagnation of trade, has not increased. The following is a statement of the produce of the duties on specific manufactured articles in 1878:—

Textile fabrics	£604,000	Furniture, &c.	£23,000
Glass and earthenware	50,000	Copper-wares	10,000
Oil	147,000	Iron-wares	10,000
Leather and leather-wares	62,000	Paper	12,500

In 1879, however, Germany has suddenly returned to an extreme protective system. The present import duties are much increased, and duties are imposed on many articles hitherto duty free. The Government hopes to make a gross revenue of about £8,000,000 by the new customs.

Excise.—The excise duties on articles of consumption have for the most part been considerably increased since 1872, especially the duty on sugar. The tax on tobacco is, however, still trifling (in 1877, £47,000). Bavaria, Württemberg, and Baden are exempt from the duties both on spirits and on malt, Alsace-Lorraine from that on spirits.

Receipts from Excise Duties.

	Beetroot Sugar.	Spirits	alt.	Malt
1872	£1,723,000	£1,631,000	£1,014,000	£601,000
1874	2,378,000	1,932,000	1,704,000	703,000
1877-78	2,774,000	2,632,000	1,758,000	922,000

Funds of the Empire.—The extraordinary funds, from which very large sums appear annually in the budget, were created after the French war. Part of the indemnity was invested for fixed purposes. The largest of these investments served for paying the pensions of the invalided, and amounted originally to £28,000,000. Every year not only the interest, but also part of the capital of this fund is expended in paying these pensions. Another fund, of about £5,200,000, serves for the construction and armament of fortresses; a third for building new houses of parliament; a fourth for the construction of railways in Alsace-Lorraine. Further, the empire has put aside £6,000,000 as a Reichs-Kriegs-Schatz, or imperial war reserve fund, which is not laid out at interest, but exists in coined gold and bullion at Spandau. The railways in Alsace-Lorraine are also the property of the empire,—France having paid an allowance

to the Eastern Railway Company of £18,000,000 for the railways brought under the control of Germany. The following table shows the state of the imperial funds at 1st March 1878—

Invalid fund	£27,870,700
Fund for armaments of fortresses	6,515,800
War reserve fund	6,000,000
Parliament House building fund	1,465,400

Imperial Debts.—The loans contracted by the North German Confederation for the war with France have long since been paid off. The extraordinary expenditure of the empire was for several years paid out of the French indemnity, but that resource is now exhausted. Accordingly, for defraying the expenses of the army and navy, the extension of the subterranean telegraphs, &c., two new loans had to be issued in 1877 and 1878, amounting to £8,760,800. There exists, besides, an unfunded debt. The law allows the imperial chancellor to effect an issue of bills of exchange for short terms to the extent of £7,500,000, and these are destined partly for the expenses of administration, and partly for the completion of the monetary reform. Since 1874 also a debt bearing no interest has been created in imperial treasury bills (Reichsschatzenscheine), which are to be substituted for the paper currency issued by the separate states. At that date only four states—Lippe, Lubek, Hamburg, and Bremen—had no paper currency. Prussia had in 1872 only £3,000,000 of paper currency, or 2s. 6d. a head, but in the minor states the proportion was higher, reaching in Saxo-Coburg-Gotha 10 3s. a head, in Anhalt 14s., in Mecklenburg-Schwerin 24 7s., and in Schaumburg-Lippe the very high figure of 94 8s. This inconvenience was remedied by an imperial law, ordering the states to call in their paper currency, and replacing it by the issue of imperial treasury bills, amounting to £6,000,000. For many of the smaller states this sudden withdrawal of their paper currency was too severe an ordeal. Accordingly, to these a further sum was advanced for a term of years in treasury bills, £3,338,000 was thus in circulation on the 30th September 1878.

Reform of the Currency.—The German empire adopted a gold currency by the law of the 4th December 1871. Subsequently the old local coinages (*Landesmünzen*) began to be called in and replaced by new gold and silver coins. The old gold coins, amounting to £4,550,000, had been called in as early as 1873; and the old silver coins have also been successively put out of circulation, so that none actually now remain as legal tenders but the thaler (3s.) Silver currency to the amount of £52,000,000 had been withdrawn up to the 30th September 1878, and copper coins to £157,600. To replace these there were coined up till the 30th September 1878—gold pieces, £31,900,000, silver coins, £21,380,000; nickel and copper, £2,287,900. The currency reform was at first facilitated by the French indemnity, a great part of which was paid in gold. But later on that metal became scarcer; the London gold price ran higher and higher, while silver declined. The average rate per ounce of standard silver in 1868-70 was 50 1/2s., in January 1875 only 57 1/2d., in July 1876 as low as 49 1/2d. It rose in January 1877 to 57 1/2d., but again declined, and in September 1878 it was 50 1/2d. While, therefore, the proportion of like weights of fine gold and fine silver in 1868-70 averaged 1 to 15 1/2s., it was 1 to 17 1/2s. in 1876, and 1 to 17 1/2s. in 1877, and the difference again increased in 1878.

Banking.—A new banking law was promulgated for the whole empire on the 14th March 1875. Before that date there existed 32 banks with the privilege of issuing notes, and on the 31st December 1872 £37,100,000 in all was in circulation, £25,100,000 of that sum being uncoverted. The banking law was designed to reduce this circulation of notes; £12,500,000 was fixed as an aggregate maximum of uncoverted notes of the banks. The private banks were at the same time obliged to erect branch offices in Berlin or Frankfurt for the payment of their notes. In consequence of this regulation 18 banks resigned the privilege of issuing notes, so that at present there are in Germany but 10 note-issuing banks of which 5 belong to South Germany (Frankfurt included). The Imperial Bank (Reichsbank) ranks far above the others in importance. It took the place of the Prussian Bank in 1876, and is under the superintendence and management of the empire, which shares in the profits. Its head office is in Berlin, and it is entitled to erect branch offices in any part of the empire. It has a capital of £20,000,000 in shares of £150. The following table exhibits the position of the German Reichsbank as compared with the other 18 banks at the 30th September 1878—

Banks.	Notes in Circulation.	Bullion	Excess of Notes.
Reichsbank	£8,551,350	£8,452,150	10,099,800
18 private banks	£9,895,850	7,209,450	2,186,400
Total	£18,447,200	£15,661,600	£2,785,600

Subjoined is a comparison with the great banks of England, France, and Austria at the same date—

Banks	Notes in Circulation	Bullion	Excess of Notes.
Bank of England	£26,592,000	£28,846,000	2,742,000
Bank of France	£1,250,000,000	£86,114,000	£1,163,886,000
German Reichsbank	£8,551,350	£8,452,150	10,099,800
Austrian National Bank	29,698,000	13,836,000	15,862,000

Finances of the separate States.—The budgets of the different German states are so variously arranged that it is difficult to group them on uniform principles. We extract the following particulars from the scheme published by Prof. H. Wagner in the *Almanach de Gotha* for 1874. The expenses and receipts of the empire and those of the separate states are in the two tables taken together. The first table contains the net expenses for 1872-73, the charges of collection being deducted—

Net Expenditure of German States, including the Empire	
1. Civil list and annuities to the princely families	£1,750,000
2. Dues	112,500
3. Civil service	20,200,000
4. Interest and management of the public debts	19,000,000
5. Army and navy	17,360,000

Total £48,422,500

Professor Wagner's second table gives the principal items of revenue—

Revenue	Gross Revenue	Net Revenue.
I. Revenue from public property and establishments managed by state	£	£
1. Crown land and state forests		5,300,000
2. Interest on consolidated funds, profits of loans, &c.		3,076,000
3. State lotteries		372,000
4. Products of public mines and salt works		1,210,000
5. Various state establishments		354,000
6. Post-offices, telegraph service, state railways, canals		6,288,000
II. Taxes		
1. Direct taxes	11,176,000	10,686,000
2. Excise—		
Spirits and malt	1,868,000	
Sweets and sugar	170,000	
Tobacco	1,662,000	
Other articles of consumption	86,500	
3. Customs	6,074,000	5,500,000
4. Stamps of all kinds, and fees	5,700,000	6,384,000
5. Tolls, tonnage, &c.		466,000
Total		£77,628,000

In the absence of trustworthy statistics the local taxes have not been taken into consideration in the above table. These, however, are very considerable in many cities in Germany, in consequence of recent expenditure on schoolhouses, sewerage-works, &c.

A comparison of the foregoing tables with the corresponding statistics for the United Kingdom (1874) gives the following result. The payments on account of the national debt in Great Britain formed 42·2 per cent. of the total expenditure after deducting the charges of collection. In Germany only 13·14 per cent. The army and navy in England absorb 39·3 per cent. of the expenditure (or 65·0 per cent. after deducting the charges of debt), in Germany 35·4 per cent. (or 43·7). The expenses of the national debt in England are about 17s. a head, in Germany about 6s. The expenses of the army and navy in England are about 12s. a head, in Germany 6s. The public property in domains and forests is greater in Germany than in any other state of Europe, the area of the state forests being no less than 17,600 square miles. Many of the smaller states derive more than one-half of their expenditure by the revenue from domains and forests. From this source Germany is able to meet nearly one-fifth of her expenditure (17·3 per cent.), whereas in England only 0·6 per cent. is thus obtained. On the other hand, the expenses incurred by Germany for the civil lists and for annuities to the princely families are very considerable. Germany pays 3·6 per cent. of the national income to her princes, Great Britain only 1·04 per cent. In the minor states the princely households absorb 10 to 12 per cent. of the expenditure. The proceeds of establishments managed by the state cover 17·6 per cent. of the whole expenditure in Germany, but only 2·5 in England. The proportion of direct to indirect taxes is in England as 17 to 83, in Germany as 31 to 69. But on the whole the English are taxed twice as heavily as the Germans. The gross revenue in England was, in 1874, 42s. a head, in Germany 18 1/2s.; of these sums 18 1/2s. came, in England, from customs duties, and 13 1/2s. from excise on spirits and malt (apart from the customs duties), while in Germany the corresponding figures were only 8s. and 2 1/2s.

A considerable part of the public debt of the separate states was

paid off by them after the war. In 1873 the total amount of all debts of the German states was only about £171,000,000. In this sum was included £9,500,000 of currency. The greater part of this liability has been incurred for productive purposes, particularly for the construction of railways. The railway debts (which are not directly charged on the population) were in 1873 about £96,500,000. Since then some states have gone on reducing their debts still further. Prussia, for example, has done so by more than £11,000,000. Others again, such as Bavaria, Saxony, Württemberg, and Baden have contracted new loans for constructing railways, or, as Saxony, for purchasing them. The entire debt of all the German states, including the imperial debt, at 31st December 1877, may be estimated at £220,000,000, of which sum, however, more than £140,000,000 consists of railway debt. The average sum per head will accordingly be £25, whereas in Great Britain it is £23 to £24. When the railway debts are deducted the proportion is less than £2 a head in Germany.

ARMY AND NAVY.

By the constitution of 16th April 1871 every German is liable to service (*wehrpflichtig*), and no substitution is allowed (art. 57). Every German capable of bearing arms (*wehrfähig*) has to serve in the standing army for seven years—as a rule from the end of the twentieth till the commencement of the twenty-eighth year of his age. Three of these seven years he must spend in active service, and the remainder in the reserve; after quitting the latter he forms part of the *landwehr* for five years more—the full time of military service thus being twelve years. The strength of the army on a peace footing (*friedensfuss*) was fixed in the army bill of 1874 at 401,659 (or say 1 per cent. of the population at the census of 1871) for a term of seven years ending the 31st December 1881. The number of recruits levied annually is 145,000 men. All young men who reach a certain fixed standard of higher school training, however, are obliged to serve only for one year in the active army, and these are not included in the effective strength of the army on a peace footing. Collaterally with the army there has existed since 1875 the *landsturm*, to which all men liable to service and capable of bearing arms, between the ages of seventeen and forty-two, belong, if they are neither in the line, the reserve, the *landwehr*, nor the marine. The *landsturm* is only called to arms in the event of a hostile invasion of the imperial territory being threatened or effected.

By the articles of the constitution the whole of the land forces of the empire form a united army in war and peace under the orders of the emperor. The sovereigns of the chief states are entitled to nominate the lower grades of officers, and the king of Bavaria has reserved to himself the special privilege of superintending the general administration of the two Bavarian corps d'armée; but all appointments are made subject to the emperor's approval. The 64th article of the constitution enacts that all German troops are bound to obey unconditionally the orders of the emperor, and to take the oath of allegiance accordingly. The emperor is empowered to erect fortresses in any part of the empire.

Organization of the Army.—The imperial army consists of 18 army corps, viz., the Prussian *garde-du-corps*, 13 Prussian corps (including the troops of the minor states in military convention with Prussia—Nos. 1 to 11 being Prussian, while Nos. 14 and 15 are the Baden and Alsace-Lorraine corps respectively), the Saxon corps (No. 12), the Württemberg corps (No. 13), and the 2 Bavarian corps. One army "inspection" comprises from 3 to 4 corps. Generally 1 army corps consists of 2 divisions, each of which includes 1 horse and 2 foot brigades. As a rule the infantry brigade consists of 2 infantry regiments and 2 *landwehr* regiments, the cavalry brigade of from 2 to 3 cavalry regiments. An infantry regiment consists of 3 battalions of 4 companies each; a cavalry regiment has 5 squadrons. There are many exceptions, however, to these rules, e.g., the *garde-du-corps* and the Saxon corps d'armée consist each of 1 cavalry and 2 infantry divisions, the 11th contains 3 divisions, &c. Some divisions also are stronger than others. Altogether the German army numbers 40 divisions, of which 6 are infantry, 3 cavalry,

and 31 both combined. There are in all 74 infantry and 38 cavalry brigades, and 148 infantry and 98 cavalry regiments.

Besides the troops above named, each army corps generally includes (a) 1 page or light battalion (the Bavarian army has, however, 10 of them), (b) 1 field artillery brigade; (c) 1 foot artillery regiment, (d) 1 engineer battalion, (e) 1 train battalion. The *garde-du-corps* has, in addition, two railway battalions, 1 instruction infantry battalion (*Lehrbattalion*), &c. The several field artillery brigades are not uniformly constituted, but in 12 of the 18 army corps the brigade consists of 2 artillery regiments. One of these with 8 batteries is attached to the division, while the other remains under the orders of the corps commander. This latter consists of 2 sections (*Abtheilungen*) of 3 batteries each, and a mounted division of 3 batteries. Each battery has as a rule 4 guns. A foot artillery regiment has 2 battalions of 4 companies each. There are in all 36 field artillery regiments with 801 batteries and 1206 guns, and 18 foot artillery regiments. In war time several corps are combined as "armies," the entire military force consisting then of the field or battle army, the reserve or supplementary troops (*Ersatztruppen*), and the garrison troops (*Besatzungstruppen*).

The following tables exhibit the strength of the German army on a peace footing and on a war footing respectively.

There are also 25,975 men who are not included in the latter sum-total but whose cost is defrayed by army grants. They include 4653 physicians, 838 veterinary surgeons, 1600 paymasters, &c. Nor does the table take account of the troops of the field reserves and of the *landsturm*, regarding the organization of which no details have been published; the former, which is drawn from the *landwehr*, is estimated at 250,000 men. It is calculated that Germany may put in arms at any given time two millions and a half of armed men without having recourse to the last reserves. The maximum strength of the army in the war with France was 1,350,787 men and 203,753 horses.

Fortresses.—Since the Franco-German war the fortress system has been entirely remodelled. A number of old and useless fortresses have been dismantled; several new ones have been erected along the sea-coast; and most of those flanking the land frontiers have been enlarged. The

empire is divided into nine fortress districts, each including a certain number of fortified places. The Baltic coast fortresses are Memel, Pillau, Dantzig (first-class fortress), Colberg, Swinemünde, Stralsund, Travemünde, Kiel, Fredrichsort, Sonderburg-Düppel. On the North Sea are Wilhelmshaven and the fortresses by which the mouths of the Elbe, Weser, and Ems are guarded. The eastern frontier is protected by the first-class fortresses of Königsberg, Dantzig, Thorn, and Posen, and by the secondary ones of Marienburg and Dirschau on the Vistula, and of Glogau on the Oder, which are especially intended for the protection of the railways. For the southern frontier there exist only the fortresses of Neisse, Glatz, and Königstein on the Elbe. The old inland fortresses have been abolished, except the first-class ones of Küstrin, Magdeburg, Spandau, and (for railway protection) Torgau on the Elbe. Ulm and Ingolstadt on the Danube, both first-class fortresses, are also maintained. On the western frontier Strasbourg and Metz have been fortified by a wide range of outer fortifications, and there is besides an outer line of smaller fortified places, consisting of New Breisach, Bitsch, Saarhaus, and Thionville. A second line runs along the Rhine, where there are large fortresses serving as encampments at Rastadt, Mainz, Coblenz, and Cologne, and smaller ones for the protection of the Rhine bridges at Gernersheim, Ehrenbreitstein opposite Coblenz, Düsseldorf, and Wesel. The empire thus possesses 16 fortified places of the first class serving as camps, and 27 other fortresses.

Navy.—The German navy is but of recent origin. In 1848 the German people urged the construction of a fleet. Money was collected, and a few men-of-war were fitted out; but those were subsequently sold, the German bundestag (federal council) not being in sympathy with the aspirations of the nation. Prussia, however, began laying the foundations of a small navy. To meet the difficulty arising from the want of good harbours in the Baltic, a small extent of territory near Jaldé Bay was bought from Oldenburg in 1854, for the purpose of establishing a war-port there. Its construction is now practically completed, although at enormous expense, and it was opened for ships by the emperor in June 1869 under the name of Wilhelmshaven. In 1864 Prussia, by annexing Holstein, obtained possession of the excellent port of Kiel, which has since been strongly fortified. From the time of the formation of the North German confederation the navy has belonged to the common federal interest. Since 1st October 1867 all its ships have carried the same flag,—black, white, red, with the Prussian eagle and the iron cross.

From 1848 to 1868 the increase of the navy was slow. In 1851 it consisted of 51 ships with 188 guns (among which there were, however, 36 small gunboats of 2 guns each), and with 1180 hands in all. In 1868 it consisted of 89 vessels of 563 guns, among which number there were 2 ironclads, and 43 other steamers. Since then a definite plan for the development of the navy has been set on foot, and great activity has been displayed in fitting out ships and in augmenting the personnel.

The following table shows the increase that has occurred in the navy budget since 1868:—

	Ordinary.	Extra-ordinary.		Ordinary.	Extra-ordinary.
	£	£		£	£
1868	851,000	394,000	1874	692,000	1,076,000
1869	885,000	407,000	1875	909,000	454,000
1870	470,000	637,000	1876	1,053,000	238,000
1871	536,000	660,000	1877	1,083,000	1,428,000
1872	626,000	685,000	1878-79	1,206,000	1,729,000
1873	688,000	730,000			

The personnel of the navy consisted in 1878 of 965 officers and 9265 men. There are 2 sailors divisions (Matrosendivisionen) of 79 officers and 6020 seamen and boys, a ship-boys department

(Abtheilung) of 400 hands, 2 dockyard divisions (Werftdivisionen) with 148 officers and 1718 men, and 1 battalion of marines with 1035 men. The sailors and marines are levied by conscription from among the seafaring population, which is on this account exempt from service in the army. The total sea-going population of Germany is estimated at 80,000, 48,000 of whom serve in the merchant marine at home, and about 6000 in foreign service. Great inducements to enter the navy are held out to able seamen. The following table gives the state of the navy in August 1878:—

Ships	Number	Guns	Tonnage	Horse-Power
Armour-clad ships—				
Frigates . . .	3	85	3,400 to 5,900	3,500 to 8,000
Corvettes . . .	7	20	2,400 to 5,000	3,000 to 5,000
Floating batteries	7	13	750 to 1,300	700 to 1,300
Non-armour clad ships—				
Floating battery	1	23	3,200	3,000
Docked gun vessels	11	146	1,700 to 2,800	1,500 to 4,800
Corvettes	7	62	1,000 to 1,600	800 to 2,400
Despatch vessels	5	6	330 to 1,650	350 to 1,000
Gunboats	12	30	600 to 1,200	600 to 1,100
Torpedo ships	11		24 to 800	80 to 2,300
Transport steamers	1		425	320
Sailing vessels	4	28	2,800	
Total	79	399	61,560	110,000

RELIGION.

In the official census it has been usual to return the religious creed of the inhabitants, though a few states, such as Prussia and Hamburg, omitted this particular in 1875. Official estimates indeed have been made of the religious profession of the people in these states for 1875 also, but only the census of 1867 and that of 1871 can be accurately compared. The number of persons styling themselves of no religion, or refusing to state their religion, is very small. The following table gives the results of the three last enumerations:—

Creeds	1867 Census	1871 Census	1875 Partly estimated
Protestants . . .	24,921,000	25,581,623	26,718,823
Roman Catholics	14,661,000	14,867,600	15,371,227
Dissenters	117,000	82,156	100,608
Jews	499,000	512,130	520,575
Other creeds	6,000	176	10,127
Religion not stated.		16,980	
Total . . .	40,107,000	41,058,723	42,727,360

Almost two-thirds of the population belong to the Evangelical Church, and rather more than a third to the Church of Rome. The dissenters are very inferior in numbers, amounting to only about 100,000 souls, but the Jewish element, represented by half a million ($1\frac{1}{2}$ per cent.), is more considerable than in any other state of West, North, or South Europe. The following table gives the proportion of Protestants, Catholics, and Jews in every 1000 inhabitants:—

	Rate to 1000 Inhabitants		
	Protestants.	Catholics.	Jews.
1867	621	363	12·4
1871	623	362	12·5
1875	625	360	12·2

The Protestants have increased in number by 0·4 per cent. of the population since 1867. This increase, however, must not be attributed to conversions, but rather to the greater increase of population in the Protestant provinces of Germany as compared with the Catholic ones; though at the same time the official returns of Prussia prove that conversion to the rival communion is much more frequent with Catholics than with Protestants. Three states in Germany have a decidedly predominant Catholic population, viz.,

Alsace-Lorraine, Bavaria, and Baden; and in four states the Protestant element prevails, but with 23 to 33 per cent. of Catholics, viz., Prussia, Wurtemberg, Hesse, and Oldenburg. In Saxony and eighteen minor states the Catholics number only from 1 to 3·3 per cent. of the population. The following table gives the respective numbers of Protestants and Catholics according to the census of 1871:—

States.	Protestants	Roman Catholics	Rate per 1000 of Population	
			Prot	Cath
Alsace-Lorraine	270,699	1,235,097	175	797
Bavaria	1,312,592	3,464,364	276	712
Baden	491,008	942,560	336	645
Prussia	18,041,215	8,268,309	650	335
Wurtemberg	1,245,860	553,442	687	304
Hesse	552,399	255,080	636	279
Oldenburg	240,962	71,027	766	226
Saxony and minor states	5,890,808	94,621	978	17
Total	25,581,623	14,867,600	623	392

From the above figures little can be inferred as to the geographical distribution of the two confessions. On this point it must be borne in mind that the population of the larger towns, on account of the greater mobility of the population since the introduction of railways and the abolition of restrictions upon free settlement, has become more mixed.—Berlin, Leipzig, Hamburg, &c., showing proportionally more Catholics, and Cologne, Frankfurt, Munich, &c., more Protestants than formerly. Otherwise the geographical limits of the confessions have been but little altered since the Thirty Years' War. In the mixed territories those places which formerly belonged to Catholic princes are Catholic still, and *vice versa*. Hence a religious map of South Germany looks like an historical map of the 17th century. The number of localities where the two confessions exist side by side is small. Generally speaking, South Germany is predominantly Catholic. Some districts along the Danube (province of Bavaria, Upper Palatinate, Swabia), in southern Wurtemberg and Baden, and in Alsace-Lorraine are entirely so. These territories are bordered by a broad stretch of country on the north, where Protestantism has maintained its hold since the time of the Reformation, including Baireuth or eastern Upper Franconia, Middle Franconia, the northern half of Wurtemberg and Baden, with Hesse and the Palatinate. More the average proportion of Protestants to Catholics is two to one. The basin of the Main is again Catholic from Bamberg to Aschaffenburg (western Upper Franconia and Lower Franconia). In Prussia the western and south-eastern provinces are mostly Catholic, especially the Rhine province, together with the government districts of Munster and Arnsberg. The territories of the former principality of Cleves and of the countship of Mark (comprising very nearly the basin of the Ruhr), which went to Brandenburg in 1609, must, however, be excepted. North of Munster, Catholicism is still prevalent in the territory of the former bishopric of Osnabruck. In the east, East Prussia (Ermland excepted) is purely Protestant. Catholicism was predominant a hundred years ago in all the frontier provinces acquired by Prussia in the days of Frederick the Great, but since then the German immigrants have widely propagated the Protestant faith in those districts. A prevalently Catholic population is still found in the district of Oppeln (89 per cent.) and the countship of Glatz, in the province of Posen (64 per cent.), in the Polish-speaking "circles" of West Prussia, and in Ermland (East Prussia). In all the remaining territory the Catholic creed is professed only in the Eichsfeld on the southern border of the province of Hanover, and around Hildesheim.

Protestant Church.—The adherents of Protestantism are divided by their confessions into Reformed and Lutheran. To unite these the "church union" has been introduced in several Protestant states, as for example in Prussia and Nassau in 1817, in the Palatinate in 1818, and in Baden in 1822. Since 1817 the distinction has accordingly been ignored in Prussia, and Christians are there enumerated only as Evangelical or Catholic. The union, however, has not remained wholly unopposed,—a section of the more rigid Lutherans who separated themselves from the state church being now known as Old Lutherans. In 1866 Prussia annexed Hanover and Schleswig-Holstein, where the Protestants were Lutherans, and Hesse, where the Reformed Church had the preponderance. The inhabitants of these countries opposed the introduction of the union, but could not prevent their being subordinated to the Prussian oberkirchenrath (high church-council), the supreme court of the state church. Subsequently the official returns have been thus classified:—

(a) Members of the Evangelical State Church	1875
United	16,086,900
Lutherans	13,286,620
Reformed	2,905,260
(b) Separatist Lutherans (Old L.)	465,120
(c) Separatist Reformed	40,680
	35,080

The separatists are thus not numbered among dissenters. A synodal constitution for the Evangelical State Church was introduced in Prussia in 1875. The oberkirchenrath retains the right of supreme management. The ecclesiastical affairs of the separate provinces are directed by consistorial boards. The parishes (*pfarreien*) are grouped into dioceses (*sprengel*), presided over by superintendents, who are subordinate to the superintendent-general of the province. Prussia has sixteen superintendent-general. The ecclesiastical administration is similarly regulated in the other countries of the Protestant creed. Regarding the number of churches and chapels Germany has no exact statistics, but in 1867 it was estimated that there were 12,959 places of worship in Prussia.

Roman Catholic Church.—There are six archbishoprics within the German empire:—Breslau (where the archbishop has the title of prince-bishop), Gnesen-Posen, Cologne, Freiburg (Baden), Munich-Freising, and Bamberg. The eighteen bishoprics are—Ermland (see at Franconburg, East Prussia), Kulm (see at Pelnin, West Prussia), Fulda, Hildesheim, Osnabruck, Paderborn, Munster, Limburg, Treves, Metz, Strasburg, Spiers, Wurzburg, Ratisbon, Passau, Eichsfeld, Augsburg, Rottenburg (Wurtemberg). An apostolic vicariate exists in Dresden. In recent years numerous convents, especially in Prussia, have been suppressed. The order of the Jesuits is interdicted in Germany.

Old Catholics.—After the infallibility of the pope had been proclaimed as a dogma by the Vatican council in 1871, several communities as well as individuals declared their secession from the Roman Church. They are called Old Catholics, and they have selected a bishop who has been acknowledged by most of the states. At the 1st of January 1877 the denomination had 121 congregations with 56 clergymen and 16,557 adult male adherents, so that we may fairly estimate the total number of Old Catholics at a little more than 50,000.

The number of Greek Catholics was 2560 in 1871.

Dissenters.—There is no uniformity in the state returns of the several denominations, and detailed statements are wanting for Wurtemberg, Alsace-Lorraine, and eight of the lesser states. In the sixteen remaining states there were in 1875 21,000 Mennonites (particularly in East and West Prussia and the Palatinate), 10,451 Baptists, 3000 Irvingites, 4000 Herrnhuter (Moravian brethren), and 1600 members of the Church of England. The Mennonites had

increased from 14,000 in 1871. Besides these there were about 6800 German Catholics, 3600 Freethinkers, and more than twenty-five sects represented by from 100 to 500 members.

Jews.—It is in the towns that the Jewish element is chiefly to be found. They belong principally to the mercantile class, and are to a very large extent dealers in money. Within the last thirty years their wealth has grown to an extraordinary degree. They are increasingly numerous in Hamburg, Berlin, Frankfort, Breslau, Königsberg, and Fürth. Though still, in fact at least, if not also by law, excluded from many public offices, especially from commands in the army, they nevertheless are very powerful in Germany, the press being for the most part in their hands. Some towns of the Marienwerder and Posen districts contain from 20 to 30 per cent of Jews. By far the greater number are found among the Slavs in the east; in the west they appear chiefly in Hesse, Baden, and Alsace.

LANGUAGES.

The German-speaking nations in their various branches and dialects are found to extend in a compact mass along the shores of the Baltic and of the North Sea, from Memel in the east to a point between Gravelines and Calais near the Straits of Dover. On this northern line the Germans come in contact with the Danes who inhabit the northern parts of Schleswig within the limits of the German empire. A line from opposite Sonderburg in the isle of Alsace to Tondern in the west will nearly form the boundary between the two idioms. The German-French frontier traverses Belgium from west to east, touching the towns of St Omer, Courtrai, and Maestricht. Near Eupen, south of Aix-la-Chapelle, it turns southward, and near Aarlon south-east as far as the crest of the Vosges mountains, which it follows up to Belfort, traversing there the watershed of the Rhine and the Doubs. In the Swiss territory the line of demarcation passes through Biel, Freiburg, Saanen, Leuk, and Monto Rosa. In the south the Germans come into contact with Rhaeto-Romans and Italians, the former inhabiting the valley of the Vorder-Rhein and the Engadine, while the latter have settled on the southern slopes of the Alps, and are continually advancing up the valley of the Adige. Carinthia and Styria are inhabited by German people, except the valley of the Drave towards Klagenfurt. Their eastern neighbours there are first the Magyars, then the northern Slavs and the Poles. The whole eastern frontier is very much broken, and cannot be described in a few words. Besides detached German colonies in Hungary, the western parts of that country are held by Germans. The river March is the frontier north of the Danube from Pressburg as far as Brinn, to the north of which the German regions begin near Olmütz,—the interior of Bohemia and Moravia being occupied by Czechs and Moravians. In the Prussian provinces of Silesia and Posen the eastern parts are mixed territories, the German language progressing slowly among the Poles. In Bromberg and Thorn, in the valley of the Vistula, German is prevalent. In West Prussia some parts of the interior, and in East Prussia a small region along the Russian frontier, are occupied by Poles (Kassubians in West Prussia, Masurians in East Prussia). The German tongue is also fast invading the Lithuanian territory, and in a short time no people speaking that idiom will be found to the left of the river Memel. The total number of German-speaking people, within the boundaries wherein they constitute the compact mass of the population, may be estimated, if the Dutch and the Flemings be included, at 56 millions.

The geographical limits of the German language thus do not quite coincide with the German frontiers. The empire

contains about 3½ millions of persons who do not make use of German in everyday life, not counting the 290,000 resident foreigners. The non-German languages have their representatives only in Prussia, Saxony, and Alsace-Lorraine. No census since 1861 has given the statistics of the different languages spoken in the first mentioned country; and, in regard to Alsace-Lorraine also, the figures are based upon estimates only. The following table gives the results of semi-official estimates for 1875:—

Languages	Persons	Proportion to 1000 Persons
German	39,100,000	921 66 4 4 6
Polish	2,600,000	
Wendic	140,000	
Czech	50,000	
Lithuanian	150,000	
Danish	150,000	4
French	250,000	6
Total—Natives	42,440,000	
Foreigners	290,000	

From this it will be observed that the Poles form a considerable part of the population,—about 60.1 per cent in the district of Oppeln, 59.8 in Posen, 49.6 in Bromberg, 37.8 in Marienwerder, 27.3 in Danzig, 21.9 in Gumbinnen, 17.1 in Königsberg, and 4.3 in Breslau. The Wendes, who inhabit Lusatia, are decreasing in number,—in the Saxon district there were 52,097 in 1871, and in 1875 only 50,737. The Lithuanians are likewise diminishing on the eastern border of East Prussia. Czechs are found only in Silesia on the confines of Bohemia. The French are represented in Lorraine and Upper Alsace, and on the Belgian frontier.

EDUCATION.

In point of intellectual culture Germany ranks high. Much is done by the Government for the promotion both of primary and of secondary education, yet there are no exact statistics, however, of the educational establishments, or of the expenditure incurred in connexion with them. In regard to the latter the sums which figure in the Government budgets are not the only contributions which must be considered; for in most of the states the several local communities provide from their own resources for primary instruction and for many of the higher schools, while many of the superior institutes have funds of their own not included in the budget. School instruction is obligatory on the whole people, but in many districts there is still a scarcity of teachers and some want of efficient control. The total number of primary schools is estimated at 60,000, and that of pupils at 6,500,000, or 150 pupils to every 1000 inhabitants. Some provinces exhibit a larger proportion; in Saxony, Thuringia, Brunswick, Rhineland, and Westphalia there are from 165 to 175 pupils to every 1000 inhabitants. In Bavaria, Posen, East and West Prussia, Brandenburg, on the other hand, there are only from 130 to 130. A good criterion of the school instruction is to be found in the statistics of the annual levies of recruits. The following table shows the number of recruits during the years 1876-78 who were unable to read and write:—

	Number of levied recruits able to write and read.		Number of levied recruits unable to write and read.	
	In German Language.	In other Languages only.	Number.	Rate to 10,000 Recruits.
1876-78	130,176	6,368	3,311	237
1876-77	130,939	6,283	2,975	212
1877-78	134,189	6,292	2,470	173

It will be seen from the above that the number of illiterate recruits has considerably decreased during the last three years. The figures given compare very favourably with those of other European countries. In 1872 the number

of illiterates was 4·6 per cent. in the army, and 2·3 in the navy, the corresponding numbers in France being 23 and 14 per cent. In England 23 per cent. of the marines could neither read nor write in 1865, 4 per cent. could only read, and 37 per cent. could write but imperfectly. In Austria only 28 per cent. of the recruits could write, and in Russia scarcely 10 per cent. had any school education. But the provinces of Germany differ much from one another in this respect. Education is very inferior in the eastern Polish districts. During the three years from 1875-78 in the districts of Posen, Bromberg, and Oppeln there were in all 10·7, 9·24, 8·02 per cent. of illiterates among the recruits, in the provinces of West and East Prussia 8·77, 8·06, 7·80. After these the rate takes a long leap to 3·18, 3·17, 1·94 in Alsace-Lorraine and the Palatinate. In 1877-78 there was no considerable district in Germany which sent so many as 1 per cent. of illiterates. The most satisfactory state of matters is to be found in Saxony, Thuringia, Baden, and Wurttemberg, and especially in the last two. Wurttemberg had only one recruit among 6000 that was unable to read.

The census in Prussia in 1871 proves primary school instruction to be much better among the Protestants than among the Catholics, as will be seen in the following table:—

Illiterates of 10 Years and under.	Males	Females	Percentage of corresponding Population.		
			Males.	Fem.	Total.
Protestants	300,117	493,400	4·9	8·3	6·7
Catholics	464,766	685,636	11·3	16·4	13·2
Jews	7,870	16,648	4·9	9·4	7·2
Others	995	2,846	3·7	9·4	6·2
Total	863,943	1,396,434	7·1	11·1	9·2

Unremitting attention is being paid to the improvement of primary schools (*volkschulen*), although many of the eastern districts are still destitute of these in the rural localities. Not long ago the position of teachers of primary schools was very unsatisfactory; and the supply of masters was unequal to the demand. In recent years much has been done in all the states to effect a reform on this state of matters. In 1875 there were 170 seminaries in Germany for the training of schoolmasters. But this number is insufficient, for it may be estimated that 5000 to 6000 new appointments are required annually, if one master is not to have charge of more than 60 children. Saxony has the greatest number of institutions of this kind (15). Within the last few years many municipalities have begun to found schools of a somewhat higher rank for the lower classes of the town population, called middle schools.

There are four different kinds of schools for the higher branches of education. The gymnasias supply preparatory training for the universities, the foremost place in the course of instruction being assigned to the classical languages; but French, English, and mathematics are also taught, and some attention is given to natural science, history, and geography. Their constitution dates back to very remote times, and but few and slight alterations have been made in their schemes of study since the beginning of the present century. Officials, judges, clergymen, teachers, and physicians for the most part receive their early education at the gymnasium. In 1878 there were 360 gymnasias in Germany, or 1 for every 600 square miles and every 117,000 inhabitants. Central Germany has the largest proportion, 1 for every 75,000 inhabitants. To these must be added the *progymnasias*, about 90 in number. The same studies are prosecuted in these, but the highest classes of a gymnasium are wanting. Of more recent growth is the system of *realschulen*, where Latin is the only ancient language

taught, the other branches being modern languages, especially French and English, mathematics and natural philosophy, geography, and modern history. These schools have long enjoyed great popularity. They are classified as of the first and of the second order. In the former a pupil remains generally for nine or ten years, as in the gymnasias; and those who pass the highest examination are allowed to enter the universities, but only to study the modern languages, mathematics, and natural sciences. In 1878 there were 129 *realschulen* of the first order, mainly in Saxony, Rhineland, Berlin, and Hanover. The *realschulen* of the second order prepare pupils for those professions which do not require a university course. On the average a pupil leaves school in the seventeenth year of his age. Besides these institutions, which are increasing every year, there is a considerable number of technical schools (*gewerbeschulen*). Their purpose is purely industrial; drawing, mechanics, mathematics, physics, and chemistry are among the subjects of instruction, languages being excluded. There are, moreover, schools of commerce, navigation, and agriculture in different towns. The military law relating to the one year's volunteers has had an important influence on the attendance at all these institutions. In 1879 there were 878 schools with the privilege of furnishing pass certificates to such volunteers; of these 360 were gymnasias, 129 were *realschulen*, and about 40 were private schools. Exact and uniform statistics of the higher schools do not as yet exist. Many of the last-mentioned institutions are maintained partly or entirely at the expense of the municipalities, and by far the greater number are denominational, Protestant ones prevailing. The following table shows the number of Prussian schools in 1875 maintained severally by the Government, by the municipalities, and by other funds:—

Denomination.	Number of Middle Schools in Prussia maintained by		
	Government.	Municipalities.	Private Funds.
Protestant	100	199	16
Mixed	18	38	..
Catholic	43	31	2
Jewish	2
Total	161	268	20

Universities and Higher Technical Schools.—Germany owes its large number of universities, and its widely diffused higher education to its former subdivision into many separate states. Only a few of the universities date their existence from the present century; the majority of them are very much older. Each of the larger provinces, except Posen, has at least one university, the entire number at present being 21. All have four faculties except Münster, which has no faculties of law and medicine. As regards theology, Bonn, Breslau, and Tübingen have both a Protestant and a Catholic faculty; Freiburg, Munich, Münster, and Würzburg are exclusively Catholic; and all the rest are Protestant. The following table gives the names of the 21 universities, the dates of their respective foundations, the number of their professors and other teachers, and of the students attending their lectures during the summer session 1878, arranged according to the numbers in attendance:—¹

¹ The teaching staff was classified as follows: ordinary professors 957, extraordinary professors 463, honorary professors 41, private teachers (*privat-docenten*) 438, language and exercise masters 86. The following table gives the number of the students in the different faculties for 1878:—

1. Students of Protestant theology	1,738
2. " Roman Catholic theology	699
3. " law, politics, and forestry	6,168
4. " medicine, surgery, and pharmacy	8,727
5. " philosophy, philology, history, geography, mathematics, and natural science	7,297
6. Unmatured students (chiefly at Berlin)	2,988

Universities.	Dates of Foundation.	Number of Professors and Teachers.	Number of Students.
1. Berlin, Prussia.	1810	215	4,381
2. Leipzig, Saxony.	1409	160	2,948
3. Munich, Bavaria.	1826	186	1,896
4. Breslau, Prussia (1702)	1811	106	1,250
5. Tübingen, Württemberg.	1477	88	1,144
6. Bonn, Prussia.	1818	100	1,075
7. Göttingen, Prussia.	1737	120	1,009
8. Würzburg, Bavaria.	1402	66	960
9. Halle, Prussia.	1697	107	944
10. Heidelberg, Baden.	1386	110	808
11. Strasburg, Alsace-Lorraine.	1872	90	736
12. Königsberg, Prussia.	1544	89	671
13. Jena, Thuringian states.	1558	78	570
14. Greifswald, Prussia.	1456	61	534
15. Marburg, Prussia.	1527	71	458
16. Freiburg, Baden.	1457	57	454
17. Erlangen, Bavaria.	1743	64	415
18. Giessen, Hesse.	1607	55	347
19. Münster, Prussia.	1780	30	332
20. Kiel, Prussia.	1665	69	261
21. Rostock, Mecklenburg.	1419	41	157
Total.		1,918	20,826

A number of technical high schools rank along with the universities; they all took their rise in the course of the present century, and usually bear the name of Polytechnicum. To the number of these belong the academies of industry (founded 1821) and of architecture (1798) in Berlin, and the polytechnics at Hanover, Brunswick, Aix-la-Chapelle, Darmstadt, Karlsruhe, Stuttgart, Munich, and Dresden.

Among the remaining higher technical schools may be mentioned the mining academies of Freiberg in Saxony, of Berlin, and of Clausthal in the Harz, and the academies of forestry at Neustadt-Eberswalde, Münden on the Weser, Tharand near Dresden, and Hohenheim near Stuttgart, and at Brunswick, Eisenach, Giessen, and Karlsruhe. Schools of agriculture have also been attached to several universities, the most important being at Berlin, Halle, Göttingen, Königsberg, Jena, Poppelsdorf near Bonn, Munich, and Leipzig.

Libraries.—Mental culture and a general diffusion of knowledge are extensively promoted by means of numerous public libraries established in the capitals, the university towns, and other places. The most celebrated public libraries are those of Berlin (800,000 volumes), Munich (800,000 volumes and 22,000 manuscripts), Göttingen, Dresden, Stuttgart, Hamburg, Strasburg, Frankfurt-on-the-Main, Breslau, Götting, and Wolfenbüttel.

Societies.—There are also numerous societies and unions, some being of an exclusively scientific character, and others being designed for the popular diffusion of useful knowledge. The academies of science in Berlin, Munich, Göttingen, and Leipzig are Government institutions. Ample provision is made for scientific collections of all kinds in almost all places of any importance, either at the public expense or through private munificence.

Observatories.—These have in recent years been considerably augmented. There are 22 observatories in the empire, viz., at Altona, Berlin, Bonn, Borkamp in Schleswig, Breslau, Dantzic, Düsseldorf, Götting, Göttingen, Hamburg, Kiel, Königsberg, Leipzig, Lübeck, Mannheim, Marburg, Munich, Potsdam, Schwerin, Spiers, Strasburg, and Wilhelmshaven.

Book Trade.—This branch of industry, from the important position it has gradually acquired since the time of the Reformation, is to be regarded as at once a cause and a result of the mental culture of Germany. Leipzig is the centre of the trade. The number of booksellers in Germany was not less than 5196 in 1878, among whom were 1546

publishers. The following table will show the recent progress of German literary production, and its proportion to that of other European states.—

	Number of Published Works.			
	Germany.	France.	Gr. Britain.	Italy.
1866	10,563	11,267	4,439	4,084
1870	10,068	8,831	5,082	4,318
1872	11,127	10,559	4,812	6,429
1877	13,925			
1878	13,912			

Newspapers.—While in England a few important newspapers have an immense circulation, the newspapers of Germany are much more numerous, but individually command a far more limited sale. Leaving out of account insignificant local papers, Germany in 1878 possessed 600 newspapers published daily, or two to three times a week; of these only 90 were published in South Germany. Berlin alone produces 44 newspapers. Most readers receive their newspapers through the post-office or at their clubs, which may help to explain the smaller number of copies sold. Only 50 of the 600 daily newspapers print more than 10,000 copies, and only 20 more than 20,000.

Fine Arts.—There are many academies which have for their object the promotion of a taste for painting, sculpture, architecture, and music, and the improvement of the technique of art. The largest academy is now that of Berlin. The three schools of painting (*malerschulen*) are represented by the academies of Berlin, Munich, and Düsseldorf. Other academies for painting are to be found in Dresden, Karlsruhe, Weimar, and Königsberg. The chief musical academy is at Leipzig. Numerous museums of art and collections of pictures exist in the country, but there is no concentration of these as in London or Paris. Although the collections in Berlin have of late years been considerably enriched, they do not equal in their number of celebrated originals the galleries of Dresden, Munich, and Cassel. An archaeological institute is maintained by the imperial Government at Rome and at Athens, and recently Germany has done much for the advancement of archæology by the part she has taken in the excavations at Olympia.

Bibliography.

Maps.—The topographical maps of Prussia and of some North German states (scale 1:100,000) are not yet quite completed. The South German states have for the greater part finished their topographical maps, scale 1:50,000. Other good special maps, though not quite completed, are—the maps of Central Europe by Reymann (1:200,000) and by Liebenow (1:300,000), and of Germany by Stieler (1:750,000) and by Havenskiöld (1:800,000).

Physical Geography.—There is still wanting a sufficiently detailed work on the physical geography of Germany as a whole, although there are some excellent descriptions of the separate provinces. For general information we may mention—Cotta, *Deutschland's Natur*, 2 vols., 1855; Daniel, *Deutschland*, 1878; Kutzner, *Das deutsche Land*; Von Klöden, *Geographisches Handbuch*, vol. II., 1875; Neumann, *Das deutsche Reich*, 2 vols., 1874; Pöschel and Andree, *Atlas der deutschen Reiches*, 2 parts, 1876-78.

Statistics.—Since the year 1871 there has been established in Berlin an imperial office for statistics which does excellent work. Most of the figures in the foregoing article have been derived from these official returns. From 1871 to 1878 the same office has published 30 volumes in 4to, under the title of *Statistik des deutschen Reiches und Monarchie der Statistik des deutschen Reiches*. But the returns do not give statistics under all the heads in which the separate states collect them. Much valuable geographical, statistical, and topographical information is given in Neumann's *Das deutsche Reich*. The most recent summaries are to be found year by year in the *Annuaire de Gotha*.

Topography.—Rudolph's *Vollständiges Ortslexicon von Deutschland*, 2 vols., 1870, is exact and very ample. The separate states have published lists of all places (towns, villages, hamlets, farms), according to the census of 1871. *Das Reichs-Postgebieth*, issued by the General Post-Office, 1878, containing about 7000 places, exclusive of Württemberg and Bavaria, forms an excellent topographical and statistical handbook. (H. W.)

PART II.—HISTORY OF GERMANY. By JAMES SIME.

Entered according to Act of Parliament of Canada, in the year 1879, by ADAM & CHARLES BLACK, Edinburgh, Scotland, in the office of the Minister of Agriculture.

Ancient Times.

The people whom we call "the Germans," and who call themselves "die Deutschen," are a branch of the Teutonic race, which, again, belongs to the great Aryan family. At what time the Teutons broke away from their Aryan kinsfolk we have no means of knowing. In the 4th century B.C., when they are first mentioned, they were settled along the shores of the Baltic Sea; but long before that time the race must have scattered itself far and wide over the countries now known as Scandinavia and Germany, and the Scandinavians and the Germans were gradually marked off from each other by important differences in language, in customs, and in institutions.

At the time of Tacitus, whose *Germania* is our chief authority as to the condition of ancient Germany, central Europe was in the possession of a large number of German tribes. These tribes did not call themselves by a common name. The word "German" is of Celtic origin, meaning, according to some philologists, "shooters," according to others, "neighbours." It seems to have been applied by the Gauls in the first instance to a particular German tribe with which they were in conflict, and afterwards to the whole people. The word "Deutsch" (Goth. *Thiuda*, the people) does not occur till the 9th century, and was not used in the sense now given to it for some time later. Although without a common name, the ancient Germans believed that they had a common origin, all of them regarding as their forefather Mannus, the first man, the son of the god Tuisc. Mannus was supposed to have had three sons, from whom had sprung the Istevones, the Ingævones, and the Hermiones. These groups were without political significance, but they seem to have marked real distinctions. The Istevones were the tribes with whom the Romans were brought most into contact, occupying, as they did, both banks of the Rhine. The lands held by those of them on the left bank were divided by the Romans into "Germania Superior" and "Germania Inferior," the chief tribe of the latter being the Ubii, who had an important settlement on the site of what is now Cologne. On the right bank, from the Lippe to the Ruhr, were the Usipetes and Tencteri, and to the north of them the Sicambri and the Bructeri; the land now called Hesse appears to have been inhabited by the Chatti. On the island formed by the Meuse and an arm of the Rhine were the Batavi. The second great group, the Ingævones, among whom were the Frisii, the Chauci, and the Cherusci, were settled along the shores of the North Sea, and inland along the banks of the Weser and the Ems. The Hermiones were much more numerous than either of the two other groups; they held the greater part of central and eastern Germany, reaching as far as the Vistula and the Carpathians. Most prominent among them were the Suevi, a great confederation of tribes which included the Marcomanni, the dwellers in what is now Bohemia, and the Sennones, who held what is now Lusatia and Brandenburg. Other Hermiones were the Hermunduri, in and around the Thuringian forest; the Lombards, at the mouth of the Elbe; the Vandals, at the upper parts of the same river; the Heruli, to the west of the Vistula; and the Qundi, in what is now Moravia.

The ancient Germans were a tall and vigorous race, with long fair hair and what Tacitus calls "forcibly blue eyes." They wore mantles of fur or of coarse woollen stuff, thrown over the shoulders and fastened by a thorn or a pin. Their dwellings were wooden huts of slight construction, the inner walls of which they roughly coloured, and in which cattle were sometimes accommodated with the family.

War and the chase were the favourite occupations of the men; and when engaged neither in fighting nor in hunting they often lay idly by the hearth, leaving peaceful work to women and to males incapable of bearing arms. They liked social gatherings, but after a time conversation usually gave place to drunkenness, quarrelling, or excessive gambling. Although violent and cruel in moments of excitement, they were rarely treacherous, and in the ordinary intercourse of life they appear to have been kindly and considerate. They cherished the memory of illustrious ancestors, and listened often and with delight to songs celebrating their famous deeds.

The bulk of the people were freemen, who alone exercised political rights. They inherited their position, and the sign of their dignity was that they always carried arms. A limited class of freemen were nobles, whose sole privilege seems to have been that they were more respected on account of their birth than their neighbours, and more easily acquired a leading place in public life. Each freeman had slaves, who were chiefly prisoners of war and their offspring, and persons condemned to slavery for crime. They had no legal rights as against their owners, but in practice they were well treated. The *Liti*, composed mostly of freedmen, stood between freemen and slaves. A freeman necessarily either possessed land or was a member of a family that did; the *Liti* could only hold land of a superior with whom they shared the produce. If any one killed a noble, a freeman, or one of the *Liti*, he had to pay to the relatives a fine called afterwards the *wergeld*, and the amount was determined by the class to which the murdered man belonged.

Great importance was attributed to family relations. Instead of the bridegroom looking for a dowry, he was expected to present his bride with a valuable gift which should remain her property throughout life. The wife was completely subject to her husband, and if she proved unfaithful, custom allowed him to cut off her hair and to whip her through the village in which she lived; but this punishment had seldom to be inflicted, the German women being famous for their chastity. They were treated as friends by their husbands, who had a high respect for their judgment, and whom they often accompanied in distant expeditions. The children, over whom the father had absolute control, were hardly trained, boys being early taught the use of weapons, and girls devoting themselves to domestic duties. Relatives were held in great esteem, and when the head of a household died, it was considered their duty to guard the interests of his family.

Many freemen lived apart from all others with their families and dependants, but the majority were grouped together in villages. The land around a village—is "mark"—originally belonged to the community, and was periodically divided among the inhabitants. About the beginning of the Christian era, however, the arable land was mostly in the possession of individual freemen, the forests and waste places being almost the only common property. A number of villages made a hundred, and the "gau," if the word existed so early, may have been a higher division, although it was more probably the name for the whole land of the tribe. Each village had its chief, elected by the freemen, but the important chiefs were the heads of the hundreds and the head of the tribe, whom the freemen also appointed. Some tribes had kings, but their power had no other source than that of other chiefs, nor was it more extensive; their only distinction was that they were chosen from particular noble families supposed to have sprung from the gods.

Character of people.

The chiefs of the hundreds and of the tribes had the right of gathering around them bands of followers, and they never failed to exercise it, vying with each other in the number and quality of the young men whom they attracted to their service. These young men were generally eager for active duty, and if the tribe was at peace an adventurous chief would often give them an opportunity of distinguishing themselves by taking part in the wars of other communities. They swore to be faithful to him, and he in return supplied them with horses, with armour, and with food. The authority of the chief was extremely limited, the constitution of ancient German society being essentially democratic. Every village, hundred, and tribe had its periodical assembly, and these assemblies were attended by all freemen, no one of whom had higher rights than his fellows. Before the meeting of the assembly of the tribe, the king or other supreme chief would consult with the chiefs of the hundreds, who formed his council; but the final decision rested with the freemen, whom they could influence only by persuasion. At this assembly the chiefs were elected; and in its presence freemen clad their sons in the armour which indicated that they had attained the rights of citizenship. It declared war and made peace, permitted the chiefs with their followers to undertake warlike expeditions, and settled all disputed cases of justice.

Army. The army was not a distinct institution; it was made up of the whole body of freemen, all of whom were liable at any moment to be called to service. Each had a long shield and spear, the cavalry having no other armour. The infantry were provided also with missile weapons, of which they made dexterous use, and occasionally wielded clubs and battle-axes. The men of each hundred kept together in war, and were commanded by their chief, the supreme command being undertaken by the head of the tribe, or entrusted to a "herzog" appointed by the army. In the event of several tribes uniting, a herzog was chosen by the chiefs of the allied communities. The Germans rushed upon their enemies with fury, shouting or chanting as they did so, and adding to the noise by putting their shields to their mouths. To throw away the shield in panic was perhaps the worst crime of a German; and most persons guilty of it committed suicide in an agony of remorse and shame.

Religion. The religion of the ancient Germans was essentially the same as that of their Scandinavian kinsmen, but our sources of information respecting it are few and imperfect. The highest place among the gods was held by Wotan or Odan, the Scandinavian Odin. The Romans identified him with Mercury, and the mediæval German writers, in referring to him, follow their example. He was the god of the air and of the sky, and was looked upon as the giver of the fruits of the earth. He delighted in battle and in the chase, and was represented as an imposing figure in a large white mantle, riding upon a white horse. Along with him the Germans worshipped Donar, the Scandinavian Thor, to whom Tacitus seems to refer in speaking of Hercules as a German divinity. He was the god of thunder and of the weather, and was armed with a hammer or thunderbolt. In later times the Germans supposed him to be Jupiter. He presided over marriage, and controlled the operations of agriculture; and to him were sacred the oak and the mountain ash, the bear and the ram. Another great divinity was Ziu or Tiu, the Scandinavian Tyr, the god of war, whom Tacitus speaks of as Mars, and whose symbol was the sword. Tacitus says that a powerful goddess called Nerthus was worshipped on the shores of the Baltic; he also mentions Isis as a goddess of the Suevic tribes. Both names evidently refer to the same divinity. On the coasts her symbol was a ship; inland, it was a

waggon, in some districts she was represented with the plough. Like Donar, she presided over marriage; she also watched over the house and the fields, was the giver and protector of children, and ruled the world of the dead. At a later time she was known to the Saxons as Frig or Frigg, to the Franks as Holda, to the Bavarians as Perchta,—the first name indicating her freedom of manner, the second her kindness, the third her splendour. In the Scandinavian mythology Frigg is the wife of Odin; and to this day, it is said, the peasants in certain parts of Low Germany speak of Fru Fricke, the wife of the wild hunter Wod. The mythology of the Germans, like that of the Scandinavians, included the three sisters of fate, two of whom were fair and good, the third dark and evil. Beneath the gods were giants, elves, and dwarfs. After death, it was believed, good men were received into Walhalla, and by good men were meant warriors who never shrank in battle—above all, warriors who died fighting. The Germans were profoundly influenced by their religious faith, and both in daily life and on special occasions attended scrupulously to the duties and precautions it was supposed to involve. Each god and goddess had his or her own festival, and their images were preserved in sacred groves. Sacrifices were offered to them, and their will was discovered by means of lots, the neighing of wild horses and the flight of birds. Priests, without dominating the whole of life, exercised considerable influence, especially when the freemen met in public assembly, and when they were advancing against an enemy.

Roman Period.

The Cimbri and the Teutones, who appear to have wandered from the northern coasts of Germany, were the first German tribes with whom the Romans came into contact. In rather less than half a century after their final defeat by Marius, Ariovistus, a bold and powerful Suevic chief, crossed into Gaul with his followers to aid the Sequani against the Ædui. The latter were defeated, and in reward for his services, he received from the Sequani a third of their best lands. It soon became obvious that his friendship was dangerous, and in 58 B.C. his terrified allies appealed for aid to the new proconsul, Julius Cæsar, who had just inflicted a crushing defeat on the Helvetii. When Cæsar sent to him proposing a personal interview, the barbarian haughtily answered that he himself had better come which Cæsar quickly did. And the issue was that the army of Ariovistus was utterly beaten, and that he escaped with difficulty, severely wounded, across the Rhine, and soon afterwards died. Cæsar crossed the Rhine twice, but left no permanent mark of his invasions. He thoroughly subdued the Germans on the left bank, and from this time the whole people began to be powerfully affected by their mighty neighbours, many of them taking service in the Roman army.

The first serious attempt to conquer Germany was made by Augustus, who, after he rose to supreme power, wanted occupation for his legions. He began by conquering Rhætia and Noricum, Celtic countries along the southern borders of Germany, extending northwards through what is now German Austria and Bavaria to the Danube. Drusus, who, with Tiberius, executed this conquest in the summer of 15 B.C., was then entrusted with the task of subduing Germany. Deciding to reach the interior of the country by means of the sea and the northern rivers, he cut a canal between the Emsel and the Rhine; and for the protection of Gaul he built no fewer than fifty forts along the latter river. Many of the tribes were at enmity with one another, and in his first expedition in 12 B.C. he was able to form an alliance with the Friesi against the Chauci and the Bructeri. In three different expeditions in the

immediately following years he found other native allies, and with their help mastered so many positions that the conquest of the whole country must have seemed quite certain. After the death of Drusus in 9 B.C., Tiberius conquered the Tenceteri and Usipetes; and at a later time he not only subdued the Sicambri, but settled 40,000 of them at the mouth of the Rhine, where they lived under Roman rule. A good many of the Istevones were now overcome, while others entered into a more or less compulsory alliance with Rome; and it is probable that, if great generals had represented the empire, Germany would soon have shared the fate of Gaul. Quintilius Varus, who, in 6 A.D., was placed at the head of the Roman troops in Germany, lost all the advantages gained by his predecessors. He had held office in Syria, where he had ruled with great harshness; and fancying that he might act in the same way towards the fierce tribes of the north, he roused among them a bitter hatred of the Romans. They found in Arminius, a son of the chief of the Cherusci, a leader of extraordinary bravery and resource. He had been a Roman soldier, and had so distinguished himself—perhaps in wars against his countrymen—that he was made a citizen and knight. He formed the design of freeing his people, and soon came to a secret understanding with influential Cheruscan and other chiefs. In the year 9, in the month of September, Varus, who had been told that a northern tribe was in revolt, was led at the head of his legions into the Teutoburg Forest. Here the Germans were lying in wait for him; and everything was in their favour, the narrow defiles having caused disorder among the troops, and the ground having been made muddy by heavy rains. The battle which ensued lasted three days, during which the Romans were altogether destroyed, and Varus, in despair, killed himself by falling upon his sword.

The despairing cry of Augustus—"Varus, Varus, give me back my legions!"—testifies to the consternation which this defeat caused at Rome, where it was expected that the barbarians would take a terrible revenge for the wrongs they supposed themselves to have suffered. The Germans, however, were too much occupied with internal disputes to think of any enterprise beyond their own country; and in the year 14, after Tiberius had become emperor, Rome again assumed the offensive. Germanicus, the son of Drusus, crossed the Rhine, and defeated the Marci. He returned in the year 15, when he was joined by the Chanci and other tribes, who fought for him as zealously as his own soldiers. Thusbolda, the wife of Arminius, fell into the hands of Germanicus, and was sent as a prisoner to Rome. This intensified the hostility of the young chief, who now exerted to the utmost his vast influence to stir up against the invaders his tribe and its allies. The Teutoburg Forest was again selected as the scene of an attack; and although Arminius was not victorious, he so far injured his enemy that Germanicus was forced to retreat. The struggle was resumed in the year 16, when Germanicus gained two victories. He gained them, however, at so great a cost that he and his army had to take refuge in their ships, the greater number of which were lost in a storm.

No sooner had the Romans been driven off than Arminius had to protect his people against an internal danger. Maroboduus, the chief of the Marcomanni, a man of great ambition, had by treachery or by open fighting made himself master of several neighbouring tribes. Arminius began to fear his designs, and after the defeat of Varus warned him of his peril by sending him the Roman general's head. When Germanicus finally left the country, Arminius declared war against Maroboduus, broke up his kingdom, and drove him from Germany. It is possible that Arminius himself may afterwards have wished to found a great state.

At any rate, a number of chiefs combined against him, and in the year 21, at the age of thirty-seven, he was killed.

Although the Romans did not again attempt on a large scale the conquest of Germany, they acquired great influence throughout the country, and they gradually obtained considerable possessions to the east of the Rhine and to the south of the Main. Among the tribes whom they forced to become their allies were the Frisians and the Batavians; and in the year 69 a formidable conspiracy against them was headed by a Batavian chief, Cleaudius Civilis, who, like Claudius Arminius, had been a Roman soldier. Having been on Civis. bitterly by ill-usage from the emperor Nero, he stirred up his countrymen, and he found a large number of allies on both banks of the Rhine. He struggled valiantly for a time, supported by the mysterious utterances of Velleda, a prophetess who lived in a tower in the land of the Bructeri, and excited popular enthusiasm on behalf of the enemy of Rome. At last he was overcome by the Roman general Cerialis, and the Batavians were thenceforth compelled to send recruits to the Roman army.

About a hundred years after this time the relations of the Romans and the Germans began to be reversed, the latter being the aggressors. In the Marcomannic war Marcus Aurelius opposed for thirteen years a vast host of Germans who sought to push southward into Roman territory. Meanwhile the Romans had profoundly influenced large parts of the country. They built many fortresses along their frontier, and some of these were connected by a great wall, of which there are still remnants in southern Germany. Around the fortresses grew up towns, which became the Roman centres of civilization over pretty wide districts. In towns in Rhætia, which reached from the Lake of Constance along the Danube as far as the Inn, there were important settlements at Augsburg and Regensburg (Ratisbon); Noricum, which stretched far to the east of Illyria, possessed, among other towns, Vienna, Salzburg, and Wols. Germania Superior and Germania Inferior, on the left bank of the Rhine, included Strasburg, Mainz (Mayence), Worms, Cologne, and Bonn. In the province of Belgicun, which was at least partly German, was the great city of Treves, one of the most splendid in the Roman empire, and often the residence of the emperors.

Confederations of Tribes.

The experience of the Germans in contending with the Romans taught them the necessity of some measure of union; and from the third century we hear no longer of the individual tribes which had before been famous, but of groups or confederations, each forming, for purposes of attack and defence, a single state. The Goths were one of the most important of these groups. They included many of the tribes in the eastern and north-eastern parts of Germany, such as the Vandals, the Burgundians, and the Heruli. Next to them, in the order in which they appear in history, were the Alemanni, a confederation made up of several Sævic tribes. They held the Rhine country in the neighbourhood of the Main, and were continually pushing southwards and eastwards in the hope of securing Roman lands and towns. To the north of them, on both banks of the Rhine as far as the sea, were the Franks; and to the east of the Franks, the Frisians and Saxons. The Thuringians, descendants of the Ilernudarii, inhabited the Thuringian Forest and the surrounding country.

The Goths were the first of these confederations to found a great kingdom; in the 4th century their lands stretched from the Baltic to the Black Sea. This vast state was broken up by the Huns, who poured in immense hordes from the Asiatic steppes into Europe. Urged forward by so tremendous a force, the Burgundians, the Vandals, and many of the Sævi wandered westwards early in the 5th

At-
minius.

Maro-
bodius.

century in search of new homes; and the Burgundians soon conquered from the Romans the whole of the valley of the Rhine, in which they thenceforth settled. The Vandals and the Suevi went on to Spain, the latter remaining there, but the former crossing over to Africa, where they maintained an independent kingdom for upwards of a century. Meanwhile, in a portion of Rhetia a new confederation had been forming itself, the Bavarians, who were probably in part descendants of the Marcomanni and also included some of the bands which had been driven westwards by the Huns. When the latter had settled themselves in the Gothic lands, the East Goths continued subject to them; but the West Goths crossed the Danube into Roman territory, and afterwards, under their bold chief Alaric, penetrated into Italy and seized Rome itself. In the 5th century they conquered the southern part of Gaul, and nearly the whole of Spain, shutting up the Suevi, who had preceded them, in the small part of the peninsula which now forms Portugal. In the great battle with Attila, in which the destinies of civilization were decided, they fought by the side of the Romans; and it was chiefly owing to their valour that he was forced to retreat. After his fall and the consequent disruption of his kingdom, Odoacer, the chief of the Heruli, became lord of Italy, and his authority was recognized beyond the Alps as far as Bavaria. Theodoric, the East Goth, displaced him; and to Theodoric, too, the Bavarians yielded some kind of submission. None of the German kings who planted themselves on Roman soil displayed higher statesmanship than this great sovereign, but his kingdom was built on too narrow foundations, and after his death soon gave way. The Lombards, who succeeded the East Goths in Italy, were not so brilliantly successful, but their power was more enduring.

Changes
in Ger-
many.

While these migrations were going on, great changes took place in the mother country. The Slavs, the last of the Aryan family to enter Europe, and at that time a restless and indolent race, having been stirred up by the terrific onslaughts of the Huns, had followed the general impulse towards the west. Finding many German lands vacant, they took possession of them; and so numerous were their incursions that in the 6th century the Elbe and the Saale became the eastern boundaries of Germany. Within Germany itself the confederations had greatly extended their lands. The Alemanni held both banks of the Rhine at the points where it is joined by the Moselle and the Main, and reached far into what is now Switzerland. The Thuringians had pushed down as far as the Danube, and penetrated northwards and westwards along the Elbe and towards the Weser. The basins of the Elbe and the Weser were in the hands of the Saxons, and the Bavarians steadily advanced in and around the valley of the Inn.

Franks.

More important than any of these groups were the Franks, whose destiny it was to found the German and the French kingdoms. They were remarkable for the comparatively friendly terms on which they lived with the Romans, in whose armies many of them served, and by whose side they fought the Alemanni, the West Goths, and the Burgundians. This alliance did not, however, prevent them from enriching themselves, whenever they had an opportunity, at the expense of the Romans, who were repeatedly compelled to turn against them and drive them back. The Franks who lived to the east and the west of the Rhine were called Ripuarians; those at the mouth of the Rhine and along the western shores of the North Sea were known as Salians,—both of them names whose origin is still uncertain. One consequence of the relation of the Franks to the Romans was that the kingly authority soon became higher among them than among other Germans. The Salic code, which probably belongs to the middle of the 5th century, shows us the Salian king as in all respects the centre of

his state. He was not then elected, but inherited his rights; and the only nobility which existed was that belonging to his officers and followers. The state was divided into "gaus," presided over by gaus or counts, whose duty was to administer the laws emanating from him, and to execute the sentences of his tribunal. There were still, however, popular assemblies, without whose sanction the king could not undertake any national enterprise.

Early Medieval Period.

The first Salian king of whom we know anything is Early Chlodio, who reigned about the middle of the 5th century, and whose kingdom reached to the Somme. His successor, Merwig, or Meroveus, who gave his name to the first great Frankish dynasty, fought beside the Romans and the West Goths against Attila. Childeric I., the son of Meroveus, offended his people, and appears to have fled from them and taken refuge for a time among the Thuringians. During his absence the Salians placed themselves under the Roman commander-in-chief, *Aegidius*, not as the representative of Rome, but as a personal ruler in whom they had confidence. His representative governed so badly that they were glad to welcome Childeric back. In a great battle Childeric overcame *Aegidius*, and made himself master of Cologne and Treves; but afterwards he was reconciled to the Romans, and before his death he ruled in their name in Paris. When he died in 481, his son and successor, Chlodwig (Clovis) was a boy of fifteen, but a boy of high spirit, daring and aggressive. From him, in 486, came, in wig the battle of Soissons, the blow which made an end of Roman rule in Gaul. In a few years he conquered the greater part of the country, and many of his warriors scattered themselves over it, seizing much of its most fruitful land. He turned also against men of his own race. The Alemanni having made war on the Ripuarian Franks, the latter appealed for help to Chlodwig, who gladly responded to their summons, and defeated the invaders in the battle of Zulpich. It was in this battle that he vowed, according to tradition, to become a member of the Catholic Church if the God of the Christians gave him the victory. Whether or not the tale be true, it is certain that by his baptism he owed the greater part of his amazing success; for the West Goths and the Burgundians were Arians, and the Gallic clergy, who exercised unlimited power over the popular mind, welcomed into their country an orthodox believer. As for the Alemanni, he would have annexed their whole territory, but Theodoric, the East Goth, who was interested in them, and whom he did not dare offend, warned him that he must not treat them with undue severity. He must, however, have taken the part of their territory in the neighbourhood of the Main and the Neckar, for it was henceforth known as *Franconia*. At a somewhat later date the whole of *Alemannia* was added to his kingdom. Being as unscrupulous as he was ambitious, he put to death all who had any claim to independent authority among the Franks; so that he became their sole king, and they quickly acquired the proud feeling of being the centre of a vast and growing state.

Chlodwig died in Paris, his capital, in 511, leaving four Division sons. They did not destroy the unity of the kingdom, of Frank which in its relation to the outer world continued to be ish king- dom. regarded as a single power. But each, as a king of the Franks, received a separate territory. The East or Rhenish Franks, with the Alemanni subject to them, were placed under Theodoric, the eldest. He was as valiant as his father, and not less deceitful and cruel. The great Thuringian kingdom was in his time ruled by three brothers, Hermanfrid, Berthar, and Baderich. The former of these was married to a niece of Theodoric the East Goth, Amalaberga, a kind of Thuringian Lady Macbeth. Consumed by

Salic
code.

a vehement ambition, she persuaded her husband to murder Berthar, and she would have caused the death of Baderich also, but that he knew her design and rose against the guilty pair. Hermanfried sent to Theodoric, the East Frankish king, and offered to reward him if he would form an alliance against Baderich. The offer was gladly accepted, and in a battle which followed Baderich was slain. No reward, however, was given, and Theodoric, indignant at being thus treated, vowed to be avenged. He allied himself with the northern neighbours of the Thuringians—the Saxons; and with their united forces they completely subdued the country. Theodoric himself murdered Hermanfried by pushing him off the wall of Zulpich, where they were carrying on an apparently friendly conversation, the Thuringian king having received an assurance that he would be treated with honour. Thereupon the murderer divided between himself and the Saxons the territory of the Thuringians, annexing the southern half to the Frankish kingdom. His son, Theudebert, not only maintained this conquest but added to it, after the downfall of the Gothic kingdom in Italy, that of Bavaria. The Alemanni were also made altogether subject to his rule. Thus the Saxons and the Frisians alone retained their independence.

Merovingian kings

The rights of the Franks in Germany were at first vigorously asserted; but a change soon came. The Merovingian kings carried on so many fierce wars with each other that they had little time to look after their subjects in the remote east; moreover, the rise of a great new aristocracy steadily undermined the royal power. This aristocracy was made up of the class directly associated with the king by military or court duties. They were rewarded by immense grants of land, which they held in the first instance subject to the condition of rendering faithful service, but the possession of which, in most cases, became in the end absolute and hereditary. Nowhere was the new aristocracy so powerful as in Austrasia, the eastern division of the Frankish monarchy. In Neustria, the western division, where the sovereign had to deal for the most part with a race which for five centuries had been accustomed to the despotic government of Rome, he had little difficulty in maintaining his supremacy; for the Franks settled in different districts could not but be more or less influenced by the feeling of the native population. Besides, they lived at great distances from one another, so that it was difficult to hold popular assemblies of any kind, and the powers which belonged to them were naturally transferred to the head of the state. Hence, even when the Merovingian kings of Neustria were driven into the background, and the mayors of the palace governed, the latter had high authority, and exercised it, as a rule, in the interests of the crown. In Austrasia the conditions were wholly different. There the Franks were the predominant element; and the distances were not so great but that an assembly could be rapidly summoned on every occasion of real need. Thus the important landowners of Austrasia were able to hold together, and to limit the powers of the sovereign on the one hand and of the ordinary freemen on the other. And the mayor of the palace, who was their nominee, and could at any moment be dismissed if he displeased them, usually acted as their representative and leader.

Kings under the authority of an aristocracy of this kind are not likely to be troublesome to unruly subjects; especially kings of such feeble personal character as those who, from the first half of the 7th century, nominally held the sceptre of the mighty Chlodwig. The German confederations which he and his immediate descendants had conquered soon became virtually free. They continued to acknowledge Frankish supremacy; but the acknowledgment was only formal. At the head of each

confederation was its own herzog or duke. These rulers were at first appointed by the Frankish kings, or received their sanction; but in course of time the office became hereditary in particular families. This was the case, longer than anywhere else, in Bavaria, where the ancient Agolfing family held the dual dignity from the earliest days of Frankish authority down to the time of Charles the Great. The dukes were far from being absolute sovereigns, for in Germany the freemen had retained many of their primeval rights. The assemblies of the hundred and of the confederation still exercised great authority. As among the Austrasian Franks, however, although in a less degree, the leading landowners constantly encroached upon the powers both of the poorer freemen and of the head of the state.

In the time of the great dukes of the Franks, who arose Franki to infuse new life into the decaying monarchy, there was ^{dukes.} another profound change in the position of the Germans. After the battle of Testri, in 687, in which Pippin of Herstal decided that the Frankish kingdom should not then fall to pieces, and that, in the reunited state, the Austrasian Franks should have the supremacy, the German dukes began to find that they were likely again to have a master. He made war on them, and forced them to some extent to return to the allegiance which they had all but forgotten. His successor, Charles Martel, asserted his rights with not less vigour, and added East Friesland for the first time to the monarchy. The high importance of the efforts of these two illustrious rulers was seen in the struggle of Charles Martel with the Arabs. Had the Frankish kingdom been dissolved, they would have had little difficulty in overrunning Europe; but having under him a state more or less organized, Charles was able to rally around him powerful warriors from all the districts he governed, Germany among the rest. And so, at the memorable battle of Poitiers, he saved Christendom. Other favourable results of the policy of Charles and his father were that new and vigorous life streamed towards the Gallic part of the kingdom from Germany, while the Germans were brought into closer contact than before with the higher and more refined civilization of the Gauls. Pippin the Short, the first king of the Carolingian line, although his chief fame was won in his wars with Aquitania and with Lombardy, did not neglect Germany, in which he strove to assert an authority more thorough and extensive than had been exercised even by the early Merovingian sovereigns.

After all, however, even these powerful Frankish conquerors had but imperfect success in Germany. When they were present with their formidable armies, they could command obedience; when engaged, as they often were, in distant parts of the vast Frankish territory, they could not trust to the fulfilment of the fair promises they had exacted. One of the chief causes of their ill-success was the continued independence of the Saxons. Ever since they had acquired the northern half of Thuringia, this warlike race had been extending its power. They were still heathens, and maintained all the old customs and institutions of primitive Germany. As in ancient times, they appointed a herzog only when an officer of this class was needed, in time of war; at ordinary times the chiefs elected by the freemen ruled in association with the popular assemblies. They cherished bitter hatred towards the Franks, whom they justly regarded as the enemies both of their liberties and of their religion; and their hatred found expression, not only in expeditions into Frankish territory, but in help willingly rendered to every German confederation which wished to throw off the Frankish yoke. No rebellion against the dukes of the Franks, or against King Pippin, took place in Germany without the Saxons coming forward to aid the rebels. This was perfectly understood by the Frankish rulers, who tried

717-772 again and again to put an end to the evil by subduing the Saxons. They could not, however, attain their object. An occasional victory was gained, and some border tribes were from time to time compelled to pay tribute, but the mass of the Saxons remained unconquered. This was partly due to the fact that the Saxons had not, like the other German confederations, a duke who, when beaten, could be held responsible for the engagements forced upon him as the representative of his subjects. A Saxon chief who made peace with the Franks could undertake nothing for the whole people. As a conquering race, they were firmly compact; conquered, they were in the hands of the victor a rope of sand.

Introduc-
tion of
Christi-
anity

Although, at the time of King Pippin's death in 768, the Germans were still imperfectly subdued, they had received the germs of new life; for, with the exception of the Saxons, they were then nominally Christians. The first missionaries to Germany were Irish monks. In the 7th century a number of these laboured with considerable success in different parts of the country, especially among the Alemanni and the Bavarians; and when the influence of the Franks became dominant, Frankish missionaries also began to do for the church what the warriors did for the state. The honour of converting Germany as a whole, however, belongs mainly to St Boniface, an Englishman, who in 717 began the task of his life as an assistant to another English missionary, Willibrord, in Friesland. Soon afterwards, during a visit to Rome, he received from Pope Gregory II. a commission as apostle of the Germans, and worked incessantly among the Thuringians and the Frisians. He proved himself one of the most skilful of missionaries, adapting the conceptions of Christianity to the ideas of those whom he taught. The peculiar powers of Wodan, for instance, were transferred to the archangel Michael, those of Donar to St Peter; and the chief Christmas festival, Easter, received its name from the goddess Ostara. His zeal and talent, although largely rewarded, effected less than he had hoped, so that in 723 he went once more to Rome to obtain, if possible, increased powers. Hitherto the mission in Germany had possessed an essentially independent character; Boniface now undertook to work in all things under the direction and for the benefit of the papacy. In return for this engagement he was not only made bishop of all Germans who had been or should be converted, but received from the pope a letter commanding him to Charles, the mighty duke of the Franks. The Frankish bishops, who had no wish to become subordinate to the papacy, received Boniface coldly, and threw every kind of obstacle in his way. Charles, however, believing that the conversion of Germany would be the most effectual means of establishing Frankish authority, took Boniface under his protection, and sent him forth with orders that he should be everywhere respected. Thus strengthened, he entered upon a wholly new stage of his career. He was looked upon as to some extent armed with the authority of the great warrior and ruler, and he and his fellow workers rapidly brought vast districts within the pale of the church. Possessing a high talent for organization, he would willingly have established an orderly ecclesiastical system as he proceeded; but the Alemanni and the Bavarians, among whom Christianity had made some progress before his time, would not allow him free scope for his activity; and Charles, who, by "resuming" church lands and granting them to faithful followers, had done much to weaken ecclesiastical authority in Gaul, did not wish to see it assume threatening proportions in Germany. In 738 Boniface again visited Rome, from which he returned in the following year as papal legate to the Frankish state. Armed with this new authority, he was able to some extent to give effect to his ideas. The duke of Bavaria permitted him to divide the whole of

Bavaria into the episcopal sees of Salzburg, Freisingen, Ratisbon, and Passau, and to appoint the bishops; and a little later, with the sanction of Charles, he formed also the sees of Würzburg, Erfurt, Burauburg, and Eichstätt.

Before Pippin the Short was made king, he ruled for some years in association with his brother Carlman, to whom the eastern part of the kingdom was confided. Carlman was a man of strongly religious temperament, and warmly supported Boniface. He set up by his advice bishoprics and monasteries, among the latter being the great abbey of Fulda, which, throughout the Middle Ages, was one of the chief centres of intellectual light in Germany. In 742 was held the first German council, summoned by Carlman, and presided over by Boniface. It did much for the organization of the church, and was the beginning of an important movement for the reform of ecclesiastical abuses among the Franks. Boniface wished to become archbishop of Cologne, that he might the more readily influence the Frisians; but the suggestion met with opposition, and he ultimately accepted the see of Mainz. As archbishop of Mainz and primate of Germany, he was able to foster and control the institutions he had established. The last years of his life he spent in missionary labours among the Frisians, and in 755 he died a martyr's death. By that time all German tribes, with the exception of the Saxons, professed Christianity; and the church was not only highly organized, but possessed great wealth. The old pagan faith had struck its roots too deeply into the German nature to be at once or soon completely destroyed. Traces of its influence may even yet be detected in popular beliefs and customs; and for many centuries some of its conceptions, in altered forms, had hardly less vitality than those of the Catholic creed. Christianity was, however, the dominant power, and soon became a great civilizing agency. It was a fact of high importance that its triumph was due mainly to the influence of the papacy. The German Church thus stood from the beginning in close relation to the pope,—a circumstance which added largely to his power, and which was followed by results of the utmost consequence in the later history of the nation.

Under Charles the Great (Charlemagne) a momentous era dawned in the history of the Germans. From the Charlo-
outset of his reign he had vast plans, which, however, inaguo.
were not so great as those ultimately realized. He saw at once that he could not hope to execute his schemes if on the north-eastern boundary of his kingdom there was a powerful and hostile people, ready at all times to plot against him, and to take advantage of any misfortune which might temporarily befall him. Accordingly, when the death of his brother Carlman made him, in 771, sole king, one of his first resolutions was to advance against the Saxons, and thoroughly to subdue them. It is not necessary to suppose that he went to war without an adequate special reason; for, as the Frankish and the Saxon
frontiers touched each other along the whole western and
southern boundary of Saxony, and as the Saxons were con-
tinually robbing their neighbours, pretexts for war were
always overabundant. In his first campaign in 772 he
overran the country, took the fortress of Resburg, previ-
ously supposed to be impregnable, and cast down the
Irmisul, a mysterious column to which the Saxons
attached profound religious significance. Awed by the
lordly bearing of the great Frank, by the numbers and dis-
cipline of his army, and by these proofs of his power, the
Saxons appeared to submit at once, and Charles was under
the impression that he had conquered them. Never was
there a more profound mistake; in reality, he was at the
beginning of a struggle which lasted upwards of thirty
years. Time after time, when apparently they were utterly
beaten, they rose against the invaders, and tried with des-

face.

perate energy to drive them from the country. The execution of 4500 prisoners by Charles—an act which even then was looked upon as barbarous—only deepened their resolve never to yield to his authority. At last, however, their strength was exhausted, and they had no alternative but to submit. Charles introduced among them the political institutions which were established throughout the kingdom; and they were compelled to exchange their heathenism for the Christian faith. Thus one of the greatest dangers which threatened the stability of the Frankish kingdom was overcome, and all Germany was for the first time brought under a single ruler.

Bavaria.

The part of Germany which, next to Saxony, had retained most independence was Bavaria. Its duke, Thassilo, had been on ill terms with Pippin, and, had he allied himself with the Saxons during their great conflict, he might have baffled even Charles. But he did not become troublesome until they were too weak to be of service to him. Repeated acts of treachery gave Charles a pretext for depriving him of his office, and after him no duke was placed over the country. As the dukes of the Alemanni and the Thuringians had also been displaced, Germany became, more directly than it had ever before been, subject to the Frankish sovereign. Not content with completing the conquest of the German people, he made war on the tribes which harassed their eastern frontier. The Avars, who held the greater part of what is now Hungary, were thoroughly beaten; and the Slavs, including the Czechs of Bohemia and Moravia, and the Slavonic tribes to the north of them, as far as the Baltic, were also more or less effectually forced into submission.

The imperial title.

The great step taken by Charles on Christmas Day 800, when at St Peter's in Rome he was crowned Roman emperor, intensified the allegiance of his Germans as of his other subjects; but it could not produce so powerful an impression in Germany as in Gaul. Ultimately, however, it was in Germany that the significance of the step was fully revealed, for, in becoming emperor, Charles created so splendid a prize, that later German kings could not resist the temptation to grasp at it, and its possession proved their ruin.

All the advantages which attended the rule of Charles throughout his vast empire were shared by the Germans. The border countries he formed into "marches," over which he appointed margraves, whose duty was to administer justice in his name, to collect tribute, and to extend his conquests. Germany itself was placed under counts, who did not merely, like the counts of an earlier time, execute the sentences of the royal tribunals, but themselves decided questions of justice in accordance with local laws and the capitularies of Charles. Four times a year the whole country was visited by his Missi Dominici, who reported as to the state of their districts, investigated grievances, and proclaimed the imperial decrees. Although he could not write, Charles was a man of true culture, and encouraged education by causing schools to be established in connexion with cathedrals and monasteries. These schools were modelled on the famous school of the palace over which Alcuin presided, and in which the emperor himself passed some of his happiest hours. By his magnificent basilica in Aachen (Aix-la-Chapelle), his favourite capital, and by the palaces he built there and in Ingolheim and Nimwegen, he fostered a love of art among the more advanced of his German subjects.

The clergy.

In Germany, as in Gaul, Charles treated the clergy in the spirit in which he treated the pagans; he set up and put down archbishops, bishops, and abbots, as if he were the supreme lord of the church,—which indeed, in theory as well as in practice, he claimed to be. But the church never had a truer friend. As emperor, he believed that his chief duty was to protect and to encourage it, and he was stimu-

lated to the performance of his supposed duty by the conviction that a strong spiritual power would be one of the soundest pillars of his secular authority. Hence he not only founded bishoprics and monasteries in Germany, and enriched them with magnificent gifts of land, but invested the prelates with some of the functions which properly belonged to the counts. Criminal cases they did not yet decide; but they were allowed to settle all civil disputes between the inhabitants of their territories. This policy may have been beneficial at the time, but it caused much disaster to his German successors, for the church became one of the most vigorous and obstinate powers with which they had to contend in maintaining their lawful functions.

Although in many respects one of the greatest of statesmen, Charles was of thoroughly despotic temper; more than any previous Frankish king he set himself against popular liberties. Hitherto all Germans had had the right of attending national assemblies or diets; this common freedom was now excluded, and only the great nobles, spiritual and secular, were summoned. Even they had but slight influence. They had the right of advising, but Charles himself originated and decided; and he would not brook opposition, although, indeed, so commanding was his presence, and so high the moral authority conferred by his great deeds, very little opposition was ever offered. Popular assemblies of all kinds he discouraged, transferring their functions to the counts. Not only were the rights of freemen limited, but severe hardships were imposed upon them by Charles's incessant warlike expeditions. At any moment they were liable to be dragged from their homes to some distant corner of the empire; and while they were away, their fields lay neglected, and their families suffered grinding poverty. What made this evil most galling was the fact that his pressure was very unequally felt. Well-off freemen knew how to purchase exemption from the counts, part of whose business was to see that the ranks of the army should be properly filled. It is true that Charles treated severely offences of this kind; but in such an empire as his, it was impossible even for his Missi Dominici to find out every case of injustice. Thus the burden of his many wars fell to the largest extent on the poorer class of freemen, who had but a sorry recompense in the glory their sacrifices reflected on their lord.

Not content with the general allegiance due to him as Feudal king and emperor, Charles compelled many great land-owners to take the oath of vassals; he imposed a like condition on his prelates and counts. A man might be his vassal without possessing land; but no land was granted by Charles except to those who were willing to assume this intimate personal relation. As his conquests put vast quantities of land at his disposal, especially in Saxony and on the frontiers, many freemen gladly swore to be his "men" in the hope that he would reward them for their services with extensive benefices. On the other hand, large numbers of poor freemen became the vassals of their stronger neighbours, as there was a chance that the military demands made upon them would thus be made rather less exorbitant. By these changes, due either directly or indirectly to him, Charles helped to build up that system of feudal tenures, the foundations of which had been laid by the first Merovingian kings. As in giving great temporal power to the church, so in establishing feudalism, he imagined that he was providing for the monarchy a steady support; but in the latter case, even more than in the former, he prepared weakness and humiliation for those who came after him.

After the death of Charles Germany remained for some time, in common with the other countries which composed the Frankish empire, under the direct rule of his son, Louis (Hudwig or Ludwig) the Pious. On the division of the monarchy, effected by the emperor in 817, in order

817-870. to secure the succession, Bavaria was given to his second son Louis; the other parts of Germany fell to his eldest son Lothair (Hlothar), who received also the rest of the empire, except Aquitania, which was the portion of Pippin, the youngest. This arrangement lasted until the emperor fell completely under the power of his second wife, Judith, a Bavarian princess, who intrigued incessantly to obtain for her son Charles—afterwards “Charles the Bald”—a position similar to that of his half brothers. The emperor at last, at the expense of his son Lothair, marked off an important territory for this inconvenient child. In the wars which followed, Louis the Bavarian firmly maintained his rights; but he disapproved the cruel harshness with which his father was treated by Lothair. In Germany the emperor was highly esteemed,—especially in Saxony, where he softened the rigorous system introduced by Charles, by sanctioning as far as possible a return to ancient popular institutions. The result was that when he was virtually deposed by Lothair, and afterwards not only deposed but humiliated almost beyond endurance, the Germans warmly supported Louis the Bavarian in insisting that the emperor should be restored to imperial rights. For his services on these occasions Louis received extensive additions of territory, and had he continued to be fairly treated, he would have been the most effectual support of his father's power. But the spirit of the gentle-hearted emperor was broken by misfortune, and when Pippin of Aquitania died, he was easily persuaded by Judith, who had come to an understanding with Lothair, to sanction a division of the empire by which his son in Germany would have been confined strictly to his original possession of Bavaria. Louis instantly revolted; and it was in marching against him that the emperor fell sick and died, in 840, on a small island on the Rhine opposite Ingelheim. The last words of the dying sovereign were a message of forgiveness to his rebellious son.

Lothair at once assumed the imperial dignity, and showed that he intended to demand the complete submission of his brothers, Louis and Charles. They combined against him, and in the battle of Fontenay, in 841, after fearful slaughter, defeated him. The armies of the allied brothers soon afterwards met in Strasburg, where they swore to be true to each other, Louis taking the oath, so as to be understood by the army of Charles, in a language in which we find the beginnings of modern French, Charles in a German dialect.

In 843 the treaty of Verdun was signed. By this treaty Lothair retained the title of emperor, and received, in addition to the Italian territory of the Franks, a long narrow kingdom, stretching from the Mediterranean up through the valleys of the Rhone and the Rhine to the North Sea. This kingdom was called Lotharingia, a name afterwards confined to the northern part of it along the left bank of the Rhine. To the west of Lotharingia was the kingdom of Charles, which included the greater part of what is now France. Louis received most of the German lands to the east of the Rhine, with the towns and sees of Mainz, Worms, and Speirs, on the western bank.

Nothing was further from the intention of the brothers than finally to break up the Frankish state by this division. In relation to the outer world the empire was still considered a single power, as the kingdom had been after the death of Chlodwig, more than three centuries before. And, after a time, it was for a brief period reunited under one head. Still it is not an arbitrary impulse that has led historians to fix upon 843 as the date of the real beginning of the German as well as of the French kingdom. Although it can hardly be said that a true national life had yet revealed itself in Germany, at least the foundations of national life had been laid. For the first time Germany was ruled by a king who reigned nowhere else, and it could not but be

that the people should slowly acquire a sense of common interests.

Middle Mediæval Period.

Keen animosity soon revealed itself between Louis and Charles the Bald, and on one occasion when the former, the accepting the invitation of certain West-Frankish nobles, rashly invaded his brother's territory, he was made prisoner. He escaped without dishonour only by the intercession of Lothair II., the emperor Lothair's second son, who, after his father's death, had received the greater part, and ultimately the whole, of Lothair's kingdom to the north of Italy. When Lothair II. died in 869, Charles the Bald pounced upon his territory; but Louis the German had naturally something to say to this seizure of the whole prize, and in 870 the rival brothers signed the treaty of Mersen, by which Louis became possessed of most of Lotharingia or Lorraine. Germany at this time assumed very nearly the proportions which it maintained during the Middle Ages. On the east its boundaries were the Elbe and the Saale, to the west it reached to and included the valleys of the Meuse and the Moselle, taking in, among others, the important towns and dioceses of Utrecht, Aix-la-Chapelle, Metz, Strasburg, and Basel. Franconia, which reached eastward from the Rhine through the valleys of the Neckar and the Main to the Saale, and extended also a little to the west of the Rhine, occupied the central position, and, as the home of the Franks, was the most important division of the kingdom. To the north and north-east of it was Saxony and Thuringia; to the south, Alemannia, or, as it now began to be called, Swabia, and to the east of Swabia, in the valley of the Inn, Bavaria. There were five archbishops, those of Mainz, Treves, Cologne, Salzburg, and Bremen.

Louis, who was on the whole the worst of the grandsons of Charles the Great, ruled his kingdom vigorously and efficiently. During his reign the Frankish empire was vexed throughout nearly its whole extent by the Northmen, whom the fame of Charles the Great had held in awe, but who now swept the coasts of northern, southern, and western Europe with persistent fury. The East-Frankish kingdom was, however, much less troubled at this time than the kingdom of the West Franks; the main evil with which Louis had to contend was the arrogance of his Slavonic neighbours. Exactly to the east Slavs of Franconia, from the Saale to the Oder, were the Sorabi, and to the north of them, between the Elbe and the Oder, the Wiltzi and Abotrites; while along the Baltic coast, as far as the Vistula, in what is now Pomerania, were the Wends. To the south of the Sorabi, behind the Bohemian Forest, were the Czechs of Bohemia and Moravia. All these Slavonic tribes Charles the Great had either thoroughly subdued or made tributary; and of course Louis the German claimed supremacy over them. But it was hard to make his claims good. While he was a very young ruler, a vigorous duke—Molmir—acquired a position of great power among the Moravians. Soon after the signing of the treaty of Verdun, Louis, becoming alarmed at the growing influence of this chief, advanced against him, and put in his place a chief named Rastislav, on whose allegiance he thought he could rely. But on his way back he was defeated by the Bohemians, who were on good terms with the Moravians. From this time the Moravians were a source of incessant anxiety to him. Rastislav extended his kingdom far to the east, and formed alliances with the Bulgarians and even with the Byzantine emperor; at the same time he stirred up the Bohemians and the Sorabi against Louis, and built strong fortresses on his western frontier. This gallant chief, after much fighting, at last fell into the hands of his enemies, who put out his eyes, and caused him to end his

days in a monastery. But his successor, Svatopluk, was not less energetic, and Louis was never able to overmaster him.

The emperor Lothar's successor in the empire was his eldest son Louis II, who received as his kingdom the Frankish possessions in Italy. After his death Charles the Bald adroitly managed to secure the imperial crown. This happened in 875, almost immediately before the death of Louis the German. Having succeeded so easily in regard to the supreme title, Charles fancied he might be able to unite the whole empire under his rule. But Louis had divided Germany between his three sons, Carlman, Louis, and Charles; and the second of these met Charles the Bald on the field of Andernach, and by a decided victory convinced the West Franks that it was useless to hope for dominion east of the Rhine. The same son of Louis the German forced Charles the Bald to give up such portions of Lorraine as had been ceded to him by the treaty of Meerssen, so that the right of possessing the whole of this important territory, which included the best part of what had been Austrasia, was vindicated for the Germans. The two eldest sons of Louis soon died, and the kingdom passed into the hands of the youngest, Charles the Fat, a prince of indolent habits and feeble mind. He crossed the Alps, however,

Charles
the Fat.

and was crowned emperor; and, as the Northmen were at this time tormenting the West-Frankish kingdom, and no descendant of Charles the Bald was fit to cope with them, Charles the Fat was invited to become king of the West Franks. He thus ruled, with the exception of Burgundy, which at this time became an independent state, the whole empire of Charles the Great; but the mighty fabric could not exist without the genius which had built it up. In Germany also the Northmen had made themselves more and more troublesome. Time after time their raids had penetrated far up the Rhine; they had plundered Cologne and Treves, and laid their horses over the grave of the great Charles himself, in his own beautiful basilica. His degenerate great-grandson adopted the policy of buying them off, and when he reached Paris, to the disgust of his subjects, he pursued the same course. It happened that his brother

North-
men.

Carlman had left an illegitimate son, Arnulf, whom he had made ruler of Carinthia, a country lying to the east of Bavaria. This young noble, who inherited the undaunted spirit of his forefathers, was indignant at the cowardice of his uncle; and when the latter, in 887, summoned an assembly in Tribur, Arnulf, instead of obeying the summons, marched at the head of a powerful army against the emperor. Deserted even by his ministers, and unable to offer the smallest resistance, Charles was dethroned, and in a week or two afterwards died; and Arnulf, notwithstanding his illegitimacy, became king. For some time after this, Germany was still called East Francia, and the western kingdom West Francia, but they never again had a common ruler; they were now in all respects separate, independent states. The empire of Charles the Great had fallen to pieces.

Arnulf, following the example of Charles the Fat, went to Rome and was made emperor. He could exercise but little authority in Italy, however, and soon returned. In 890 the Northmen desolated the valleys of the Meuse and the Moselle, and Arnulf, instead of buying them off, sent against them a powerful army. As it was defeated, he himself took the command in the following year. The Northmen occupied a strongly entrenched camp near Louvain; and Arnulf's force, consisting mainly of cavalry, seemed to be quite powerless. Leaping from his horse, he induced his men to fight beside him on foot; and they were so stimulated by his valour that for the first time the dreaded enemy fled, leaving thousands of bodies on the field. They never returned in such numbers as to be again a national peril. The emperor had also to wage war with

the Moravians, but his efforts here were not crowned with like success. By this time the fierce and warlike Magyars had become a terror to eastern Europe, and it occurred to Arnulf to ask for their alliance. They gladly assented; and with their help he overcame one of the three reigning sons of Svatopluk, and contrived to detach from Moravia the Bohemians, the Sorabi, and other Slavs whom Svatopluk had joined to his kingdom. But at the time of his death, in 899, he had not succeeded in breaking up the state established by this powerful warrior and his predecessor.

During the nominal reign of Louis the Child—the last of Louis the Carolingian dynasty in Germany (899–911)—the German people passed through one of the darkest periods of their history; for when the Magyars heard that Arnulf had been succeeded by a child, they swept into Germany in vast numbers, and fearful was the havoc they caused in every part of the kingdom. At such a time as this it happened that there was no leader around whom the nation could rally; it was virtually defenceless, and year after year savage hordes returned, bearing away with them as much plunder as they could carry, and driving before them as many prisoners as they could control. Where the Northmen had whipped with cords, these barbarians lashed with scorpions.

During the wars with the Magyars, the Northmen, and Growth, the Slavs, feudalism made rapid advances in Germany. Even in the days of Louis the German and Arnulf it was impossible for the sovereign to protect at all times every part of the kingdom. The people themselves were obliged to rise against their enemies, and, as in old times, they appointed herzogs or dukes for special warlike expeditions. These leaders, being chosen from the ancient ducal families, naturally began to think of restricting the power of which their fathers had been deprived; and, as there never was more urgent need of strong local rulers, they found no great difficulty in gratifying their ambition. The first reigning duke of whom we hear is Otto of Saxony, a country not only liable, like the rest of Germany, to the attacks of the Magyars, but specially exposed to the Scandinavian sea-robbers and the northern Slavs. This duke ruled over both Saxony and Thuringia. Soon afterwards we hear also of dukes in Bavaria, in Swabia, in Lorraine, and last of all, in Fræconia. Having unusual opportunities of acquiring new lands, the dukes increased their power by granting them as fiefs to vassals on whom they could depend; and many independent landowners were glad to obtain their protection by offering them homage. Multitudes of the humbler class of freemen either were forced to change the tenure of their possessions into a feudal tenure, or did so in order to escape from still greater evils. Thus, when Louis the Child died, the feudal tenure of land was the prevailing system in nearly all parts of the country. Even those who held their offices and lands immediately of the monarch, like the dukes themselves, might still, in theory, be deprived of both; but in reality they asserted almost complete independence, rendering only such service to their lord as he could force from them, or as suited their convenience. The royal authority, nominally great, had become but a shadow of the authority exercised by the early Carolingian kings.

Had Germany had no powerful external enemy, it is probable that it would now have lost the slight measure of unity to which it had attained. While Louis lived, the dukes were virtually kings in their duchies; and their natural tendency would have been to make themselves absolute rulers. But, threatened as they were by the Magyars, with the Slavs and Northmen always ready to take advantage of their weakness, they could not afford to do without a central government. Accordingly the nobles assembled at Forchheim, and by the advice of Otto, the aged duke of Saxony, Conrad

Arnulf

911-936, of Franconia was raised to the throne (911-918). He had some excellent qualities, and in quieter times would have done good service to Germany; but he was rash and impulsive, and far too ready to submit to priestly influence. The dukes of Bavaria, Swabia, and Lorraine were not present at his election; and the choice displeased them, probably because he was likely to prove considerably more powerful than they wished. Rather than acknowledge him, the duke of Lotharinga or Lorraine transferred his allegiance to Charles the Simple of France; and it was in vain that Conrad protested and despatched armies into Lorraine. With the help of the French king the duke maintained his ground, and, for the time, his country was lost to Germany. Bavaria and Swabia yielded, but, mainly through the fault of the king himself, their submission was of brief duration. The rise of the dukes had been watched with extreme jealousy by the leading prelates. They saw that the independence they had hitherto enjoyed would be much more imperilled by powerful local governors than by a sovereign who necessarily regarded it as part of his duty to protect the church. Hence they had done everything they could to prevent the dukes from extending their authority, and as the government was carried on during the reign of Louis the Child mainly by Hatto, archbishop of Mainz, they had been able to throw considerable obstacles in the way of their rivals. They now induced Conrad to force a quarrel both upon Swabia and upon Bavaria, and the result was a series of wars in which he had only partial success. What was incomparably worse, his clerical advisers involved him in a struggle with Henry, duke of Saxony, son of the duke to whom he chiefly owed his crown. Henry was a man of great personal charm, a just ruler, strong, and brave. The Saxon people were devoted to him; and his influence over them was intensified by the virtues of his beautiful wife, to whom he was known to be passionately attached. Conrad committed a profound mistake in making an enemy of a man like this; and he lived to regret his error. On his death-bed he recommended the Franco-German nobles to offer the crown to Henry, whom, with fine generosity, he recognized as the only man in the kingdom who could cope with the anarchy by which he had himself been baffled.

The nobles of Franconia acted upon the advice of their chief and king, and the Saxons were very willing that the duke they loved so well should rise to still higher honours. Henry I. (918-936) was one of the best kings Germany ever had, a born statesman and warrior. His ambition was of the noblest order, for he sank his personal interests in the cause of his country; and he knew exactly when to attain his objects by force, and when by calmness and moderation. By wise concessions he almost immediately overcame the opposition of the dukes of Swabia and Bavaria; and some time later, taking advantage of the troubled state of France, he accepted the homage of the duke of Lorraine, which for many centuries afterwards remained a part of the German kingdom.

Having established internal order, Henry was able to turn to matters of even more pressing moment. In the very first year of his reign the terrible Magyars, who had continued to scourge Germany during the reign of Conrad, broke into Saxony and plundered the land almost without hindrance. In 924 they returned, and this time, by good fortune, one of their greatest princes fell into the hands of the Germans. Henry restored him to his countrymen on condition that they should agree to a truce of nine years; and he had the courage to undertake to pay, during this period, yearly tribute. The heedless barbarians accepted his terms, and faithfully kept their word in regard to the immediate lands of Henry, although Bavaria, Swabia, and Franconia they occasionally invaded as before. He made admirable use of the opportunity he had secured,

confining his efforts to Saxony and Thuringia, the only parts of Germany over which he had strong control. In the southern and western German lands, towns and fortified places had long existed; but in the north, where Roman influence had but feebly extended, and where even the Franks had not exercised much authority until the time of Charles the Great, the people still lived as in ancient times either on solitary farms or in exposed villages. Such fortresses as Charles had built had been for the most part destroyed in the wars after his time, and almost the only attempts at fortification were to be found around the towers or castles of the great nobles, and the dwellings of the leading churchmen. Henry saw that, while this state of things lasted, the population could never be safe, and began in earnest the construction of fortresses and walled towns. Of every group of nine men one was compelled to devote himself to this work, while the remaining eight cultivated his fields, and allowed a third of their produce to be stored against times of trouble. The necessities of military discipline were next attended to. Hitherto the Germans had fought mainly on foot, and, as the Magyars came on horseback, the nation was placed at an immense disadvantage. A powerful force of cavalry was now raised, while at the same time the infantry were drilled in new and more effective modes of fighting. Although these preparations were carried on directly under Henry's supervision only in Saxony and Thuringia, the neighbouring dukes knew what he was doing, and were stimulated to follow his example. When he concluded that he was almost ready, he made use of his new troops, before turning them against their chief enemy, the Magyars, to punish refractory Slavonic tribes; and at this time he brought under temporary subjection nearly all the Slavs between the Elbe and the Oder. He proceeded also against the Bohemians, whose duke was compelled to do homage.

At the expiry of the truce the Magyar messengers came as usual for their tribute. They were sent away empty handed, whereupon a vast body of invaders crossed as in former years the frontier of Thuringia. Henry prudently waited until dearth of provisions forced the enemy to divide into two bands. He then swept down upon the weaker force, annihilated it, and rapidly advanced against the remaining portion of the army. The second battle was more severe than the first, but not less decisive. The Magyars, unable to cope with a disciplined army, were cut down in great numbers, and those who survived rode in wild terror from the field. The exact scenes of these conflicts are not known, but few more important battles have ever been fought. The power of the Magyars was not indeed destroyed, but it was broken, and the way was prepared for the effective liberation of Germany from an intolerable plague. While the Magyars had been troubling Germany on the east and south, the Danes had been irritating her on the north. Charles the Great had established a march between the Elbe and the Schlei; but in course of time the Danes had not only seized this territory, but had driven the German population beyond the Elbe. The Saxons had been slowly reconquering the lost ground, and now Henry, advancing with his victorious army into Jutland, forced Gorm, the Danish king, to become his vassal. The German lands were given back, and it is probable that the march of Schleswig was at this time instituted.

When this great king died, every land inhabited by a Teutonic German population formed part of the kingdom, and none of the duchies were at war either with him or among themselves. Along the northern and eastern frontier were tributary races, and the country was for the time rid of an enemy which, for nearly a generation, had kept it in perpetual fear. Vast as were these results, perhaps Henry did even greater service in beginning the growth of towns

throughout north Germany. He was not content with merely making them places of defence, he decreed that they should be centres for the administration of justice, and that in them should be held all public festivities and ceremonies; he also instituted town markets, and encouraged traders to take advantage of the opportunities provided for them. A strong check was thus imposed upon the tendency of freemen to become the vassals of great lords. This movement was made so powerful by the troubles of the epoch that, had no other current of influence set in, the entire class of freemen must soon have disappeared. As they now knew that they could in the last resort find protection without looking to a superior, they had less temptation to give up their independence, and many of them settled in the towns, where they could be safe and free. Besides maintaining a manly spirit in the population, the towns rapidly added to their importance by the stimulus they gave to all kinds of industry and trade.

Before his death, Henry obtained the promise of the nobles at a national assembly or diet in Erfurt to recognize his son Otto as his successor, and the promise was kept. Otto I. (936-973) began his reign under the most favourable circumstances. He was twenty-four years of age, and to so high a pitch of honour had Henry raised the crown that, at the coronation festival, which was of unprecedented splendour, the dukes performed for the first time the nominally menial offices known as the arch offices of the German kingdom. These peaceful relations soon came to an end. It was Henry's aim to establish the dukes in their rights, maintaining the royal authority rather by moral influence than by force. Otto, who was of haughty temper, despotic, and ambitious, seems early to have resolved that the dukes should act in the strictest sense as his vassals, or lose their dignities. At the time of his coronation Germany was virtually a federal state; he wished to transform it into a firm and compact monarchy. This policy speedily led to a formidable rebellion, headed by Thietmar, the king's half-brother, a force warrior, who fancied that he had a prior claim to the crown, and who had managed to secure a number of followers in Saxony. He was joined by the dukes of Franconia and Bavaria; and it was only by the aid of the duke of Swabia, whom the duke of Franconia had offended, that the rising was put down. A second rebellion, led by Otto's brother Henry, was supported, among other nobles, by the dukes of Franconia and Lorraine. Otto again triumphed, and derived immense advantages from his success. The duchy of Franconia he kept in his own hands, and he granted Lorraine to Conrad, an energetic and honourable count, whom he still further attached by promising him his daughter to wife. Bavaria, on the death of its duke, was placed under Henry, who, having been pardoned, had become a loyal subject and friend of his brother. The duchy of Swabia was also brought into Otto's family by the marriage of his son Ludolf with the duke's daughter. By these means he made himself master of the kingdom, as none of his immediate predecessors had been. For the time, feudalism in truth meant that lands and offices were held on condition of service; the king was the genuine ruler, not only of freemen but of the highest vassals in the nation.

In the midst of his troubles at home Otto had brought fresh perplexities upon himself by intriguing in the West-Frankish kingdom against "Louis d'Outremer." Louis responded with unexpected vigour, giving the signal for the second rising against Otto by invading Alsace. He also asserted a claim to Lorraine. When peace had been restored in Germany, Otto penetrated far into France, and received the homage of "Hugh the Great," his son-in-law; but he soon returned, and afterwards used his great influence in favour of Louis against his rebellious nobles. Much more important

than Otto's doings in France were his wars with his northern and eastern neighbours. The duke of Bohemia, after a long struggle, was brought to submission. Among the Slavs Slava, between the Elbe and the Oder the king was represented by Margrave Gero, one of his most important vassals, a warrior well fitted for the rough work he had to do, loyal to his sovereign, but capable of any treachery towards his enemies, and sometimes guilty of outrageous harshness. This remarkable man conquered most of the country north of Bohemia between the Oder and the Upper and Middle Elbe. Margrave Billung, who looked after the Abotrites at the Lower Elbe, was less fortunate, mainly because of the neighbourhood of the Danes, who, after the death of King Danes, Henry, often attacked the hated Germans. At last they made Billung prisoner, and Otto himself had to proceed against them. Their king did him homage, and he re-established the march of Schleswig, after which the margrave made rapid way among the Abotrites and Wends. Otto, having procured peace in the power of the church to reconcile conquered peoples to his rule, provided for the benefit of the Danes the bishoprics of Schleswig, Ripen, and Aarhus; and among those which he established for the Slavs was the important bishopric of Brandenburg. In his later years he set up the archbishopric of Magdeburg, which took in the sees of Meissen, Zeitz, and Merseburg.

Having secured peace in Germany, and begun the real conquest of the border races, Otto was by far the greatest sovereign in Europe; and, had he and his successors refused to go beyond the limits within which he had hitherto acted, it is almost certain they would have established a united monarchy. But a decision to which Otto soon came deprived posterity of the results which might have sprung from the policy of his earlier years. About this time Adelaide, the young and beautiful widow of Lothar, son of King Hugh of Provence, having refused to marry the son of Berengar, king of Lombardy, was cast into prison and cruelly treated. She appealed to the mighty German sovereign, and the appeal not only touched his sympathies, but awoke an overmastering ambition, since the way was thus opened for a partial restoration of the Carolingian empire. At the head of a great force, accompanied by his son Ludolf and many of his chief nobles, he crossed the Alps in 961, and descended into Lombardy. He displaced Berengar, and was so fascinated by Queen Adelaide that within a few weeks he married her. Ludolf, who had received a promise of the German crown, saw his rights threatened by this marriage, and returned sullenly to Germany. He went to an old enemy of his father, the archbishop of Mainz, and the two plotted together against the king, who, hearing of their proceedings, hastily departed, leaving Duke Conrad of Lorraine to attend to Italy. Otto had already taken the title of king of Italy, and Duke Henry, who hoped to obtain a large addition to his duchy, joined Queen Adelaide in urging him to assert the claims of the old Frankish sovereigns. Conrad, however, soon appeared with the intelligence that he had restored the Italian kingdom to Berengar, although as a fief of the German crown. This news being roughly received, Conrad took offence, and entered into the conspiracy of Ludolf and the archbishop. Otto, who did not suspect how deep were their designs, paid a visit to Mainz, and there was compelled to take certain solemn pledges which, after his escape, he repudiated. War then broke out, and the struggle was the most serious in which he had been engaged. In Lorraine, war of which Otto made his brother Bruno, archbishop of Cologne, administrator, his cause was triumphant; but everywhere else dark clouds gathered over his head. Henry of Bavaria was deserted by his vassals; in Swabia, in Franconia, and even in Saxony, the native land of the king, his own duchy, the majority sided with the rebels,

with
France.

955-973 It is extremely remarkable that the movement acquired so quickly this force and volume. The explanation, according to some historians, is that the people looked forward with alarm to the union of Germany with Italy and the empire. There were still traditions of the hardships inflicted upon the common folk by the vast expeditions of Charles the Great, and it is supposed that they anticipated like evils in the event of his empire being once more set up. Whether or not this be the true explanation, the power of Otto was shaken to its foundations. At last he was saved by the presence of an immense external peril. The Magyars were as usual stimulated to action by the disunion of their enemies; and Conrad and Ludolf were guilty of the fatal crime and blunder of inviting their co-operation. This baseness disgusted the Germans, many of whom fell away from the enterprise, and rallied to the head and protector of the nation. In a very short time Conrad and the archbishop of Mainz submitted; and although Ludolf held out a little longer, he too broke down and entreated to be pardoned. The archbishop was ordered to be closely confined in a monastery, and soon afterwards died. Lorraine was given to Bruno; but Conrad, its former duke, although thus punished, was not disgraced, for Otto had urgent need of his services in the war with the Magyars.

Defeat of
Magyars. The great battle against them was fought in 955 at the Lechfeld, near Augsburg. They had never before appeared in such numbers, and there was a strong feeling on both sides that it was to be finally settled whether the work of King Henry should be completed or wholly overthrown. After a fierce and obstinate fight, in which Conrad with many other nobles fell, the question was decided in favour of Germany and of Europe, the Magyars were even more thoroughly scourged than in the battles in which Otto's father had given them their first real check. The deliverance of Germany was complete, and from this time, notwithstanding certain wild raids towards the east, the Magyars began to settle in the land they still occupy, and to adapt themselves to the conditions of civilized life.

Otto crowned
emperor. Entreated by Pope John XII., who needed a helper against King Berengar, Otto went a second time to Italy, in 962; and on this occasion he received from the pope the imperial crown. He did not return to Germany for more than two years; and in 966 he was again in Italy, where he remained six years, exercising to the full his imperial rights in regard to the papacy, but occupied mainly in an attempt to make himself master of the southern as well as of the northern half of the peninsula.

Connection of
Germany
with the
empire. By far the most important act of Otto's eventful life was his assumption of the Lombard and the imperial crowns. His successors so steadily followed his example that the sovereign crowned at Aix-la-Chapelle claimed as his right to be afterwards crowned in Milan and in Rome. Thus grew up the Holy Roman empire, that strange state which, directly descending, through the empire of Charles the Great, from the empire of the Cæsars, contained so many elements foreign to ancient life. We are here concerned with it only in so far as it affected Germany. Germany itself never until our own day became an empire. It is true that at last the Holy Roman empire was as a matter of fact confined to Germany; but in theory it was something quite different. Like France, Germany was a kingdom, but it differed from France in this, that its king was also king in Italy and Roman emperor. As the latter title made him nominally the secular lord of the world, it might have been expected to excite the pride of his German subjects; and doubtless, after a time, they did learn to think highly of themselves as the imperial race. But the evidence tends to show that at first they had no wish for this honour, and would have much preferred had their ruler limited himself strictly to his own people.

There are signs that during Otto's reign they began to have a distinct consciousness of national life, their use of the word "deutsch" to indicate the whole people being one of these symptoms. Their common sufferings, struggles, and triumphs, however, account far more readily for this feeling than the supposition that they were elated by their king undertaking obligations which took him for years together from his native land. So solemn were the associations with the imperial title that, after acquiring it, Otto probably looked for more intimate obedience from his subjects. They were willing enough to admit its abstract claims; but in the world of feudalism there was a multitude of established customs and rights which rudely conflicted with them, and in action, remote and abstract considerations gave way before concrete and present realities. Instead of strengthening the allegiance of the Germans towards their sovereign, the imperial title was the means of steadily undermining it. To the connexion of their kingdom with the empire they owe the fact that for centuries they were the most divided of European nations, and that they have only now begun to create a genuinely united state. France was made up of a number of loosely connected lands, each with its own lord, when Germany, under Otto, was to a large extent moved by a single will, well organized, and strong. But the attention of the French kings was concentrated on their immediate interests, and in course of time they brought their unruly vassals to order. The German kings, as emperors, had duties which often took them away for long periods from Germany. This alone would have shaken their authority, for, during their absence, the great vassals seized rights which it was afterwards difficult to recover. But the emperors were not merely absent, they had to engage in struggles in which they exhausted the energies necessary to enforce obedience at home; and, in order to obtain help, they were sometimes glad to concede advantages to which, under other conditions, they would have tenaciously clung. Moreover, the greatest of all their struggles was with the papacy; so that a power outside their kingdom, but exercising immense influence within it, was in the end always prepared to weaken them by exciting discussion among their people. Thus the imperial crown was the most fatal gift that could have been offered to the German kings; apparently giving them all things, it deprived them of nearly everything. And in doing this, it inflicted on many generations incalculable and needless suffering.

By the policy of his later years Otto did much to prepare the way for the process of disintegration which he rendered inevitable by restoring the empire. With the kingdom divided into five great duchies, the sovereign could always have maintained at least so much unity as King Henry secured; and, as the experience of Otto himself showed, there would have been elements of much greater centralization. Yet he threw away this advantage. Lorraine was divided into two duchies, Upper Lorraine and Lower Lorraine. In each duchy of the kingdom he appointed a palgrave, whose duty was to maintain royal rights; and after Margrave Gero died, his territory was divided into several marches, and placed under six margraves, each with the same powers as Gero, and having extensive lands. Otto gave up the practice of retaining the duchies either in his own hands or in those of relatives. Even Saxony, his native duchy, and the chief source of his strength, was given to Margrave Billung, whose family long afterwards kept it. As a set-off the duchies to the power of the princes—for the reigning immediate vassals of the crown ranked as princes—Otto, especially after he became emperor and looked upon himself as the protector of the church, immensely increased the importance of the prelates. They received great gifts of land, were endowed with jurisdiction in criminal as well as civil cases, and obtained several other valuable sovereign rights. The

emperor's idea was that, as church lands and offices could not be hereditary, their holders would necessarily favour the crown. But he forgot that the church had a head beyond Germany, and that the passion for the rights of an order may be not less intense than that for the rights of a family. While the empire was at peace with the popes, the prelates did strongly uphold it, and their influence was unquestionably, on the whole, higher than that of rude secular nobles. But with the empire and the papacy in conflict, they could not but abide, as a rule, by the authority which had the most sacred claims to their loyalty. From all these circumstances it curiously happened that the sovereign who did more than almost any other to raise the royal power, was also the sovereign who, more than any other, wrought its decay.

Otto II. (973-983) had been crowned king and co-emperor in his father's lifetime. His troubles began within a year in Bavaria, which was now a very great duchy, not only including the valley of the Inn, but reaching up along the western frontier of Bohemia and the eastern frontiers of Swabia and Franconia as far as the Bohemian Forest. Henry, the brother of Otto I., had died soon after the battle of the Lechfeld, and had been succeeded by a young son, who, as he grew up, showed himself of so contentious a disposition that he was known as Henry the Wrangler. This young duke's sister had married the aged duke of Swabia, over whom she had absolute control, so that the younger branch of the house of Saxony had acquired an importance which the emperor could not affect to ignore. Taking offence at some action of Otto's, Henry the Wrangler conspired against him and rebelled. This first rebellion was easily put down, but Henry soon escaped from the imprisonment to which he was condemned, and then Bavaria was the scene of a war which gave occasion to great bloodshed. When at last Henry was overcome, his duchy was taken from him and granted to one of the emperor's cousins, a son of Ludolf, who had caused so much anxiety to Otto I. As this prince had already received Swabia, Otto was able, without seeming to be harsh, to deprive Bavaria of some of its importance. The southern part, Carinthia, which had hitherto been a march, was separated from it and made a duchy; and the eastern march, Austria, was also taken away, and formally made over to Liutpold, of the Babenberg family, who had already ruled it for some time, and had proved himself a faithful vassal. Another member of the same house was invested with the Nordgau, a part of Bavaria to the north of the Danube, which formed a sort of wedge between Bohemia on the one hand and Franconia and Swabia on the other. Having arrived at this settlement, Otto went to chastise the unruly Bohemians; but while he was away war was begun behind him by the new duke of Carinthia, who, forgetful of the benefits he had just received, rose to avenge the wrongs of his frond Duke Henry. The emperor hastily concluded peace with Bohemia, the duke of which did him homage; and the rising was quickly put down. Henry was made over to the keeping of the bishop of Utrecht, and Carinthia received another duke.

In his anxiety to obtain southern Italy, Otto I. had secured, as wife for his successor, Theophano, daughter of the Byzantine emperor, to whom southern Italy belonged. Otto II., having all his father's ambition with much of his strength and haughtiness, and being in the full flush of youth, longed to get away from Germany and to claim these remote possessions. But he was detained for some time by a sudden and unscrupulous invasion of Lower Lorraine in 978 by Lothair, king of France. So stealthily did the invader advance that the emperor and empress, who happened at the time to be at Aix-la-Chapelle, had just time to escape before the town was seized. As quickly as pos-

sible Otto placed himself at the head of a great army, and marched to Paris. The approach of winter compelled him to return without taking the city, which was well fortified; but soon afterwards Lothair gave up all claim to Lorraine, and peace was restored. At this time Lower Lorraine, which Otto I. had added to the crown lands, was held as a fief of the German sovereign by King Lothair's brother Charles, the last of the Carolings, whose claims to the French throne were afterwards put aside in favour of Hugh the Great.

At last Otto was able to fulfil the wish of his heart, and he did not again see Germany. His claims to southern Italy were vehemently opposed; and in 982 he suffered a disastrous defeat at the hands of the Greek emperor's subjects and their allies, the Saracens of Sicily,—saving his life by a romantic adventure. The tidings of this crushing blow cast gloom over Germany, and in the north and east the Danes and Slavs, as if by the spell by which the first Otto had held them was broken, attacked the Germans with an audacity and a determination they had never before displayed. With the Danes the Saxons were able to cope; but the Slavs, who vehemently detested the German yoke, fought with such desperate courage that much of the work effected by Margraves Billung and Cero was altogether undone. They had seemed to be decisively conquered, but two centuries passed before they were beaten back to the position to which they had been reduced in the previous reign. Such were the first fruits of the assumption of the imperial title.

About a year before his sudden death in Rome, Otto held a diet in Verona which was attended by the German princes. They would not help him in his Italian enterprise, which was extremely unpopular; but they consented to recognize his infant son Otto as his successor. This child they took back with them to Germany, and after the emperor's death he was crowned in Aix-la-Chapelle. Henry the Wrangler, as his near relative, was released from confinement and made his guardian; but as this restless prince soon showed an inclination to secure the crown for himself, the infant king was taken from him and placed under the charge of his mother Theophano. Afterwards, when she died, he lived with his grandmother, the empress Adelaide. While these two ladies acted, one after the other, as regent, the chief functions of government were discharged by Willigis, archbishop of Mainz, a vigorous prelate who had risen from a humble rank to the highest position in the German Church. He was aided by the princes of the state, each of whom claimed to have a voice in the supreme administration. Under these conditions vigorous rule was impossible; so that during the minority of Otto the royal authority was greatly weakened. In Bavaria, after the death of Henry the Wrangler, the higher vassals, without waiting for the appointment of a duke, returned to the ancient German custom, and elected Henry's son. A similar election took place in Thuringia, the head of which, although not a duke, ranked with the chief aristocracy. And along the coasts of Friesland was formed a virtually free state, which was at a later time the scene of a long-continued contest between the Frieslanders and the powerful counts of Holland. At the age of fifteen Otto III. (983-1002) was declared to have reached his majority. He had been so carefully trained in all the learning of the age that he was called "the wonder of the world," and a certain fascination still attaches to his imaginative, although somewhat fantastic, nature. His mother having imbued him with the extravagant conceptions of the Byzantine emperors, he introduced into his court an amount of splendour and ceremonial that had hitherto been unknown in western Europe. Most of his time he spent in Rome, where and how he cherished a vast scheme by which he was to do its whole extent. As the heir of the Western emperors, and

III.

1000-24. the grandson of an Eastern emperor, he fancied that he might unite the entire known world under his rule. Rome was to be its centre, and Germany but a province. In this vague design he was warmly encouraged by Gerbert, the greatest scholar of the day, whom, as Silvester II., he raised to the papal see. Silvester saw that in such an empire, with such an emperor, it would not be difficult for the papacy to become the real source of influence. Meanwhile Germany suffered severely from internal disorder and from the inroads of her rude neighbours; and when, in the year 1000—a year which Otto, with many others, feared might see the end of the world—he visited his northern kingdom, there were eager hopes that he would smite the national enemies with something of the vigour of his predecessors. But the imperial dreamer found it more interesting to go to Aix-la-Chapelle, and to descend into the tomb of the mighty Charles, beside whose gorgeously arrayed body, as it sat on its marble throne, he gave free scope to his fancy, apparently under the strange impression that his was a spirit akin to that of the worldly and resolute conqueror. One practical step he did take, but it was in a direction contrary to that desired by his subjects. The Poles, of whom we hear first during the reign of Otto I., and who inhabited the country immediately to the east of the Oder, had since his time owed a vague allegiance to the Germans. They were now ruled by Boleslaus, a chief of an aggressive and determined spirit, who by ostentatious loyalty gained the goodwill of Otto III. The latter commissioned him to conquer the Pomeranians, a duty which he gladly and effectually discharged, adding to the Pomeranians the Prussians and some of the Bohemians. The large state thus formed the emperor made independent of Germany, probably in the hope that it might form the centre for a province of his future empire. Its Christian missions were severed from the church of Germany and formed into a new Polish church; and the emperor himself founded the head seat at Gnesen, where his friend Adalbert had met a martyr's death. This was done with the sanction of Pope Silvester, who at the same time established an independent national church in Hungary, and encouraged Stephen to become the first Magyar king, by sending him from Rome a golden crown.

Poles.

Henry II.

Otto's magnificent plans received a fatal shock from the insubordination of the Romans, for whose city he designed so much honour. When he died, perhaps by poison, there was no representative of the older branch of the Saxon family, and several candidates came forward for the throne. Henry II. (1002-1024), son and successor of Henry the Wrangler, and therefore the great-grandson of King Henry I. by a younger line, managed to reach Aix-la-Chapelle before his chief rival, the duke of Swabia, and was there crowned. As he had not been elected, he was obliged to humble himself by going about among the princes and entreating their allegiance. His shattered health, querulous temper, and abject submission to priestly influence unfitted him for the great position to which he had raised himself, and his reign was an unfortunate one for Germany. For ten years civil war raged in Lorraine; in Saxony, too, torrents of blood were shed in petty quarrels. Hitherto it had been the right of the crown, when a duke or other prince died, to appoint his successor; and obviously no royal right was of greater importance. In Henry's time the principle of inheritance was virtually established in favour of the immediate vassals of the sovereign. He the more willingly made this concession because of his extravagant generosity to the church, in which, like Otto I., he looked for his main support. He had his reward in the attachment of the papacy, by which he was ultimately canonized; but he succeeded no better than his predecessors in counterbalancing the secular by the spiritual princes. In his foreign wars he

was as little prosperous as in his government at home. Boleslaus, who was now a powerful sovereign, had conquered Bohemia and Lusatia; and so anxious was Henry to win back these lands that, notwithstanding his Christian zeal, he obtained the alliance of certain Slavonic tribes by undertaking that their religion should not be interfered with. Bohemia and Lusatia were for a time detached from the Polish kingdom, but they were reconquered, and after a war of fourteen years the Poles was a greater ruler than ever. Henry went three times to Italy, and was crowned Lombard king and emperor. Before he became emperor, in order to assert his right of sovereignty over Rome, he called himself king of the Romans, and this was the designation borne by his successors until they received the higher title from the pope. Up to this time a sovereign crowned in Aix-la-Chapelle was simply "king of the East Franks" or "king of the Franks and Saxons."

The great nobles now met at Oppenheim, and elected to France the throne Conrad, a count of Franconia. The dukes of Upper and Lower Lorraine, with a number of prelates, opposed this choice; but their objections were overborne, and Conrad II. (1024-39) seemed to have no reason to dread internal enemies. Very soon, however, he had to battle with a formidable conspiracy, and during nearly his whole reign he was exposed to dangers of this kind; for he was a masterful king, looked with extreme jealousy on the rights the princes had acquired, and wished his crown to be the symbol of a genuine central authority. He was remarkably successful in contending with rebellion, and the chief cause of his success was that he allied himself with a powerful force, the significance of which had not been detected by previous sovereigns. Hitherto the vassals of great lords—the mediæ nobles—had been very much at the mercy of nobles, their superiors. Conrad, seeing that he and they had a common danger, made them more independent. It was not until nearly the end of his reign that he issued his famous edict in Italy, decreeing that no fief-holder should be deprived of his fief without judgment of his peers; but he carried out this policy from the beginning in Germany, and even from the judgment of a fief-holder's peers there was a right of appeal to the royal tribunals. The result of this policy was that the inferior fief-holders were unwilling to follow their lords against the king. Thus when Duke Ernest of Swabia, his stepson, rose against him, and appealed to his men, as in old times, to make his cause their own, they refused, urging that the sovereign was the supreme protector of their liberties. Conrad soon revealed that his object was the same as that which Otto I. long pursued,—not to do away with the dukes, but to get them, if possible, under his immediate control. The principle of inheritance he extended to the throne; and in his case it was recognized, his son Henry being crowned as his successor soon after he himself became king. To young King Henry he granted Bavaria in fief, when the reigning duke, by rising against him, forfeited his title; and afterwards, despite the bitter opposition of the nobles, he invested the same prince with Swabia, the deval family of which died out. Carinthia, being vacant, was given to Conrad's nephew. As Franconia ever since the time of Otto had remained in the hands of the sovereign, Saxony, Thuringia, and the two Lorraines were the only duchies of which Conrad was not more or less master.

When Conrad mounted the throne, the safety of Germany ^{bearing} was endangered from three different points. On the north Denmark was ruled by Canute, the great English sovereign; ^{Power.} on the east was the wide Polish state, whose sovereign Boleslaus crowned himself king, and still had possession of Bohemia and Lusatia; to the south-east was Hungary, which, under Stephen I., was rapidly becoming an organized and formidable power. Conrad was prudent enough to ask

in marriage for his son Henry Canute's daughter, and in return he ceded to Denmark the march of Schleswig. The Danes thus became the friends of the Germans, and were of service to them in keeping down the Wends. With Hungary, Conrad waged war, but not successfully, for, although a statesman, he appears to have been no great general. He was more fortunate in Poland; Boleslaus having died, the Poles plunged into a furious civil war, and he was able to turn their dissension to his own advantage. Moreover, a youthful hero, Breteslaus, an illegitimate son of the duke of Bohemia, having carried away from a convent a young German lady, a powerful noble's daughter, whom he passionately loved, and who had unbounded influence over him, was induced to place his sword at the disposal of Conrad, and by a single raid he drove the Poles from Lusatia. Lusatia and Bohemia were thus restored to Germany, and the Polish ruler, who now claimed no higher title than duke, did homage to Conrad for his lands.

In Italy Conrad was ill received, for although as emperor and Lombard king he was its lawful sovereign, the Germans were still looked upon as intruders, and by force alone they could maintain their rights. The event which at the time threw most lustre on his reign was his acquisition of the kingdom of Burgundy or Arles. It was bequeathed to him by Rudolf III., whose niece Gisela was Conrad's wife. In 1032 he was crowned, and was at once recognised by the German-speaking population. The others resisted, but in two years all opposition had been overcome, and he resolved in Geneva the homage of the leading southern nobles. This beautiful kingdom was full of prosperous cities, and its possession seemed to add incalculably to the power of the German kings; but in the end it proved an occasion of humiliation rather than of strength.

Henry III. (1039-56), who had been crowned, while his father was alive, king of Burgundy as well as of Germany, had none of the mildness and reckless impulsiveness which marred Conrad's great qualities; but he had the same decisive judgment, far-reaching ambition, and irresistible will. In the later years of Conrad, Breteslaus, the young Bohemian prince who had served him so well in Lusatia, having succeeded his father as duke of Bohemia, waged war in his own interest against the dissipated Poles, and easily brought their whole state into subjection. As he showed signs of wishing to become an independent sovereign, Henry invaded his territory, and so completely overcame him that he appeared before the king in Ratisbon, barefooted and in a penitent's garb. Henry treated him generously, and was rewarded by receiving to the end of his reign the service of a loyal vassal; and the young king also gained the good-will of the Poles by placing over them their lawful prince, Casimir, who willingly did homage for his land. The king of Denmark, too, acknowledged Henry as his feudal lord. Moreover, by several campaigns in Hungary, forced upon him by the violence of its king, Samuel, son-in-law of Stephen I., Henry brought that country for the first time, but only temporarily, into the position of a fief of the German crown. In Germany itself he acquired, during the first ten years of his reign, an authority which had been unknown since the days of Otto I. His bitter enemy, Duke Gottfried of Upper Lorraine, who conspired against him time after time, and found powerful allies in certain Burgundian nobles and in the counts of Flanders and of Holland, was beaten down; and he was able to dispense against the most powerful princes the laws of the kingdom, and to force them to maintain the public peace. Under this severe and beneficent rule Germany enjoyed a period of internal quiet such as she had probably never before experienced. But even Henry could not permanently divert from its course the central political tendency of the

age. The princes, convinced that his aim was to bring the 1024-56. duchies under his direct authority, and thus to create a monarchy which should have but one head, sullenly awaited their opportunity; and it came when, in 1052, after a ten months' siege of Presburg, he was obliged to retreat precipitately from Hungary. The influence of his great fame was shaken, and from this time he had to contend against warlike nobles. On one occasion he found out, only through the death-bed repentance of a rebel, that he was the object of a widespread conspiracy, which, had he remained in ignorance, would inevitably have succeeded. Even the moderate nobles, who had stood loyally by Conrad, were not his friends; for his wars made serious demands upon them, and his administration of justice was often stricter in regard to their class than they quite approved. Although at the time of his death he was still one of the most powerful sovereigns who ever reigned in Germany, he was obliged to adopt a conciliatory policy,—even Duke Gottfried, after all his offences, being established in his duchy.

At the beginning of Henry's reign the church all over Europe was in a deplorable condition. Simony in its basest forms was almost universally practised, and morality among the clergy was at its lowest ebb. The papacy, too, had sunk into a degraded state, its authority being annihilated, not only by the character of successive popes, but by the fact that there were at the same time three claimants of the Roman see. These evils were regarded with sorrow by Henry, who was a man of sincere and rigorous piety. Associating himself with the reforming movement which proceeded from Cluny, he not only commanded and pleaded with his prelates to put an end to abuses, but resolved to strike the evil at its root by stern exercise of his imperial rights. In 1046 he entered Rome at the head of an army which had secured for him in northern Italy such respect as had been given to no German ruler since Charles the Great, and summarily deposed the three popes whose contentions had caused scandal throughout Christendom. He then raised to the papal see the bishop of Bamberg as Clement II., who crowned him emperor; and after Clement, when death made fresh appointments necessary, three other German popes, Damasus II., Leo IX., and Victor II. Under these popes a new era began for the church and for the papacy. Behind the two latter was the stern, unfaltering, high-minded Hildebrand, who, as their adviser, silently prepared the way for his own memorable term of rule. In thus reforming the papacy, Henry III. fulfilled what was regarded as the noblest duty of his imperial office; but he also sharpened a weapon whose keen edge was first tried against his son.

The last years of Henry III. form a turning-point in German history. Great kings and emperors came after him; but none of them possessed the direct, absolute authority which he freely wielded; even in the case of the strongest, the forms of feudalism more and more interposed themselves between the monarch and the nation, and at last royal authority virtually altogether disappeared. The process was hastened by the unfortunate fact that Henry III. was succeeded by a child. The infant king, Henry IV. (1056-1106), was at first in charge of his mother, the empress Agnes, a lady of excellent qualities, but too gentle for a position which demanded the exercise of stern virtues. Her rule was jealously watched by Anno, archbishop of Cologne, a rigid churchman of imposing personality, cold to the ordinary interests of the world, but passionately devoted to his order. Discontented by the predominant influence of the bishop of Augsburg at court, he managed, by a clever trick, to get possession of the king and the insignia of royalty. Agnes, knowing his power, and deserted by her friends, retired from the regency;

1056-77 and Anno began forthwith to rule the state. By and by he was compelled by the diet to share his duties with Adalbert, archbishop of Bremen, who was not less ambitious than Anno, but was as gay, sociable, and worldly as his rival was proud and morose. In the end Adalbert made himself complete master of Henry, who thus grew up under the most diverse influences. The young king was generous, and endowed with considerable intellectual gifts; but, passing as he did from the gloomy palace in Cologne, where he lived a monk's life under terrible censures, to the palace in Bremen, where he was petted and flattered, he became wayward and self-willed. He assumed the duties of government at the age of fifteen, and soon made enemies of nearly all the chief princes. In Saxony, where, like his father, he held his court, he excited by a series of injudicious proceedings intense hostility. While the Ottos were in pursuit of the imperial phantom, a number of the crown lands in this duchy had been seized by nobles whose descendants now held them. Henry insisted on restoring these; and, as Henry I. had taken possession of the domains of his Carolingian predecessors, so Henry IV. claimed the domains of his Saxon predecessors. As if this were not enough, he built a number of fortresses which the free peasantry imagined were intended for prisons; he kept in confinement the heir to the duchy, and he persistently spoke of the Saxons in a tone of supreme contempt. All classes were thus combined against him; and in 1073 the universal discontent found expression in a vast popular assembly, attended alike by freemen and by nobles, and in which—such was the gratitude of the church for royal favours—a leading place was taken by the archbishop of Magdeburg and by the bishop of Halberstadt, the former the brother, the latter the nephew, of Archbishop Anno. Henry was surprised by a band of rebels in his fortress of Harzburg, near Goslar. Attended by a few followers he escaped, and appealed to the princes for support; but he could not compel their aid, and of free will they would grant him nothing. After tedious and degrading negotiations, in which he was accused of every kind of crime, he was at last obliged to yield the demands of his enemies. As these demands did not include the destruction of the fortresses, the peasants, fancying they were betrayed, refused to lay down their arms, and stormed through the duchy, not only battering down the detested buildings, but even destroying the chapel of the Harzburg fortress and committing acts of desecration with ruthless fury. This so alarmed the princes, both spiritual and secular, that Henry was able to advance with a large army into Saxony, where in 1075 he gained a decisive victory, and re-established the authority of the crown.

Gregory VII. While Germany was in this confused state, Hildebrand had become pope, as Gregory VII., and in 1075 he issued his famous decree against the marriage of the clergy and against their investiture by laymen,—for boldness and vastness the most magnificent policy ever devised, since, had it been effected, the pope must have become the secular as well as the spiritual lord of Christendom. So quickly had the reforming zeal of Henry III. made the papacy a power which threatened to overshadow the world. To the decree as to investiture it was impossible for any sovereign to submit, and in Germany there were stronger reasons than elsewhere for resistance. Half the land of the country was held by the clergy, and most of it had been granted to them because, in virtue of their feudal relation to the sovereign, it was supposed that they would be his most efficient helpers. Had the feudal tie been broken, the crown would soon have vanished, and the constitution of medieval society must have undergone a radical change. Henry, who had hitherto treated the new pope with excessive respect, and was believed at the Vatican

to have no strength of character, now announced his intention of going to Rome and assuming the imperial title. The pope, to whom the Saxons had been encouraged to make complaint, responded by sending back certain messengers of Henry's, with the command that he should do penance for the crimes of which his subjects accused him. Enraged by this unlooked-for arrogance, Henry summoned a synod of German bishops, who declared Hildebrand deposed. The answer was a bull excommunicating the German king, dethroning him, and liberating his subjects from their oath of allegiance.

Never had a pope ventured to take so bold a step. Its effect was within the memory of even young men that a German king had dismissed three popes, and raised, one after another, four of his own prelates to the Roman see. And now a pope attempted to drag from his throne the successor of this very sovereign. The effect of the bull was tremendous, no other was ever followed by equally important results. The princes had long been chafing under royal power; they had shaken even so stern an autocrat as Henry III., and the authority of Henry IV. was already visibly lowered. At this important stage in their contest with the crown a mighty ally suddenly offered himself, and, with innocent eagerness, they hastened to associate themselves with him. Their vassals and subjects, appalled by the invisible powers wielded by the head of the church, supported them in their rebelliousness. Henry had looked for no such result as this; he had not comprehended the influences which lay beneath the surface, and was horrified by his unexpected isolation. At a diet in Oppenheim he in vain humbled himself before the princes. They turned from him coldly, and decided that the pope should be asked to come to Germany to investigate, along with themselves, the accusations brought against him; that if, within a year, the sentence of excommunication were not removed, the king should lose his crown; and that in the meantime he should live in retirement.

Now came the strange scene at Canossa which burned itself into the memory of Europe. For three days, in the depth of winter, the representative of the Cæsars, clad in a penitent's shirt, shivered in the outer court of the Countess Mathilda's castle, entreating to be admitted into the pope's presence. No other mode of escape than complete submission to Gregory had suggested itself, or was perhaps possible; but it did not save him. Although the pope in a manner forgave him, the German princes, being resolved not to miss the chance which fortune had given them, met in his absence and deposed him, electing Rudolf, duke of Swabia, as his successor. But Henry's bitter humiliations transformed his character; they brought out all his latent capacities of malignity. From being a wilful, thoughtless lad, he became a resolute man, with many evil traces indeed of his irregular training, but with a deep consciousness of his rights, and a fixed determination to maintain them.

The war that followed—the war of investitures—was the War of opening of that tremendous struggle between the empire and the papacy, which is the central fact of medieval history, and which after two centuries of conflict, ended in the exhaustion of both powers. Its details belong more to the history of Italy than to that of Germany, but in Germany its effects were most deeply felt. It was now that the nation plucked the bitter fruits of the seed planted by Otto I. in assuming the imperial crown, and both by Otto and his predecessors and successors in lavishing worldly power upon the church. In the ambition of the spiritual and the secular princes the popes had an immense engine of offence against the emperors; and they unscrupulously turned it to the utmost advantage. The most loyal friends of the emperors were the cities. They had been

Effect of Henry's excommunication.

Scene at Canossa.

War of investitures.

steadily growing up, especially in the Rhine country and in southern Germany, and could not but see that they had far more to fear from the princes than from the crown. Hence, when Henry returned to Germany, Worms, Spire, and many other towns opened their gates to him, and freely contributed of their wealth; and towards his successors they pursued a like policy.

After several indecisive battles the rival king, Rudolf, was, in 1080, defeated and slain. Henry then carried the war into Italy, where he was crowned emperor by his own antipope, and in 1085 Hildebrand died an exile from Rome, although with unbroken spirit. In Germany two other rival kings were set up, Hermann, count of Luxembourg, and Ekbert, margrave of Meissen; but they were only partially successful, and after the death of the latter in 1089, had Germany followed her own impulses, there would have been peace. In the papacy, however, Henry had an implacable foe; and again and again, when he seemed to be on the point of complete triumph, it kindled anew the smouldering embers. His son Conrad was stirred up against him in Italy; and in Germany, when he was near the end of his days, his second son Henry was induced to head a dangerous rebellion. During his reign the first crusade took place, and he suffered severely from the pious zeal which it expressed and intensified. The movement was not in the end favourable to papal supremacy, but the early crusaders, and those who sympathized with them, regarded the enemies of the pope as the enemies of religion.

First
crusade.

Henry V.

Pope Paschal II. did not doubt, after the death of Henry IV., that he would immediately triumph, but he was mistaken. Henry V. (1100-25), who had promised, with unconscious irony, to treat him as a father, went on, like his predecessors, investing prelates with ring and staff, and, when expostulated with, replied that he could not be expected to give up a right which had belonged to all previous kings. War broke out anew, and, as in the time of Henry IV., the pope found enthusiastic supporters among the princes. One of the most ardent of these was Lothair, whom Henry V. himself had made duke of Saxony, after the extinction of the Billung line, by which for a century and a half the duchy had been ruled. Henry's chief friends were the two Hohenstaufen princes, Frederick and Conrad, to the former of whom Henry IV. gave the duchy of Swabia when Rudolf became his rival king, while the latter was created by Henry V. duke of Franconia, a country which had been attached to the crown lands since the time of Otto I. These two brothers were enthusiastic imperialists, and upheld with persistent courage the cause of their sovereign on the repeated occasions on which he went to Italy to chastise the pope. At last, in 1122, peace was restored by the concordat of Worms. By this compromise, which was forced by exhaustion upon both parties, the right of electing the prelates was granted to the clergy, and the emperor resigned the right of investing them with ring and staff. On the other hand, it was arranged that the elections should take place in the presence either of the emperor or of his representative, and that he should invest the prelates with the sceptre. The papacy was thus very far from realizing the great schemes of Hildebrand; still, even in regard to the particular question in dispute, it gained solid advantages, and its general authority was incomparably more important than it had been half a century before. For it had waged war on the emperor himself; instead of acknowledging its inferiority as in old times, it had claimed to be the highest power; it had even attempted to dispose of the imperial crown as if the empire were a fief which it granted of its good will; and it had found out that it could at any time hamper, perhaps paralyse, imperial authority, by exciting strife in Germany.

Concordat
of
Worms.

The Franconian dynasty died out with Henry V., and 1080-Lothair, duke of Saxony, was elected to succeed him. Lothair 1162(1125-37) excited the enmity of the Hohenstaufen princes by demanding that they should give up certain crown lands, which had been incorporated with their duchies. Unable to defend himself against them without help, he secured a powerful ally by granting his daughter in marriage to Henry the Proud, grandson of Welf, a prince whom Henry IV. had made duke of Bavaria. As this valiant noble soon succeeded to Bavaria, and was also invested with Saxony, he became by far the greatest subject in Germany. Nevertheless, the duke of Franconia and the duke of Swabia withstood him, and not until within three years of the emperor's death were they forced to crave for peace. A considerable portion of Lothair's reign was spent in Italy; and Innocent II. claimed that when he received the imperial crown he did so as a vassal of the pope.

Henry
the
Proud.

Nothing could indicate more clearly than this fact Decay of how much of their old power the German kings had lost. It was not past hope that even yet some of their former splendour might be restored; and for a brief period monarchy did again stand high. Still, its foundations were sapped. Incessant war, both at home and in Italy, had deprived it of its force; it had lost moral influence by humiliations of which the scene at Canossa was an extreme type. Steadily, with unwearied energy, letting no opportunity escape, the princes had advanced towards independence, and they might well look forward to such a bearing in regard to the kings as the kings had formerly adopted in regard to them.

Later Mediæval Period.

Henry the Proud was confident that he would succeed Hohenstaufen Lothair; but, by a hasty and irregular election, Conrad, duke of Franconia, was chosen king. Conrad III. (1137-52), an impulsive and not very wise ruler, found himself at once in serious perplexities. Henry the Proud, knowing that evil was designed against him, rebelled, whereupon he was declared to have forfeited his duchies; and Saxony was granted to Albert the Bear, a strong and truly great Saxon noble, while Bavaria fell to Leopold, margrave of Austria. Thus again the country was ravaged by war, for Henry the Proud, although he was unpopular in Bavaria—the duchy he had inherited—was powerfully upheld in Saxony, which, ever since Henry IV. had alienated it, had always been ready to join in an attack on the monarchy. Henry suddenly died, but the struggle was continued by his brother Duke Welf; and, but for the opportune death of some of the chief combatants, among them Leopold of Bavaria, it seemed probable that it would go hard with the king. Welf, hoping to be made Leopold's successor, agreed to a compromise, by which Saxony, with the assent of Albert the Bear, was granted to Henry—afterwards Henry the Lion—the young son of Henry the Proud. Bavaria, however, was in the end given to Henry Jasomirgott (so called from his habit of saying "Ja so mir Gott helfe!"), margrave of Austria, a rough noble, who was afterwards found to have a decidedly inconvenient temper. Welf again took to arms, and for years contended with his rival. Notwithstanding this and many other sources of confusion, Conrad was Second persuaded by the passionate eloquence of St Bernard to take part in the second crusade. He came back broken, dispirited, and near his end, to find Henry the Lion at the head of a great army, claiming Bavaria in addition to Saxony, —a claim which Conrad in vain attempted to dispute.

Germany now passed under one of the greatest of her sovereigns, Frederick Barbarossa (1152-90), nephew of King Conrad, and son of the Frederick, duke of Swabia, who had fought along with Conrad against Henry the Proud. He was a man of large and noble nature, capable, indeed,

Frederick
Barbarossa.

1152-90. if resisted, of great harshness, but a passionate lover of justice, with far-reaching ideals, ready to battle with gigantic difficulties, yet knowing how to recognize and submit to the inevitable. Allied to the Welfs through his mother, and having a personal regard for Henry the Lion, he was anxious to bring to an end the strife of the Welfs and the Hohenstaufen families, and began his reign by promising to secure for Henry the duchy of Bavaria. For his adventurous and imaginative spirit the splendour of the imperial name had an irresistible charm; and two years after he ascended the throne, in 1154, he went to Rome to be crowned emperor. After this the best years of his life were spent in Italy, where, in his obstinate struggle with the Lombard cities and with Pope Alexander III., he chiefly acquired his fame. Although it was conducted on his side mainly with German troops, it properly comes under Italian history, in which the record of his reign forms a bloody page, while his name is associated with one of the most peaceful and prosperous periods in the internal history of Germany.

Henry the Lion. The promise that Bavaria should be granted to Henry the Lion was not easily fulfilled, for Henry Jasomirgott doggedly refused to give it up. At last, however, Frederick, after his return from his first expedition to Italy, in 1156, reconciled the surly prince by detaching Austria, his native march, from Bavaria, and making it a duchy with certain special privileges,—an important step in the process by which Austria gradually became the centre of a powerful state. Henry the Lion then became duke both of Bavaria and of Saxony. This prince often gave offence by a haughty and aggressive disposition, but few German dukes won so true a title to the good-will of posterity. Since the time of Otto II. and Otto III. the Slavonic countries to the east of Saxony had been very imperfectly held in subjection. Henry devoted himself to the conquest of the territory along the shores of the Baltic, and he succeeded as no one before him had ever done. But he was not a mere conqueror; he built towns and encouraged those which already existed, founded bishoprics in the newly-won lands, and planted in them bodies of industrious colonists. While he was thus at work, a similar task was fulfilled a little to the south of him by Albert the Bear, the first margrave of Brandenburg, who, by just and energetic rule, worthily prepared the land for its great, although far-off, destinies.

Frederick's relations to other countries. Early in his reign, by settling a dispute between two brothers who claimed the crown of Denmark, Frederick brought the king of that country once more into the position of a vassal of Germany. He broke into Poland also, and compelled its ruler to do homage, and, in return for great services rendered in his Polish campaign, raised the duke of Bohemia to royal rank,—a change which in no way affected his duties to the German crown, but which gave him a certain precedence over all other subject princes. The king of Hungary, although no attempt was made to subdue him, became a useful ally of Frederick. Thus the ancient fame of Germany, which was lost during the confusion that came after Henry III., was to a large extent restored in the neighbouring countries. Frederick reasserted the royal authority in Burgundy, and added to the kingdom, by right of marriage, Upper Burgundy, or, as it was afterwards called, Franche Comté. Internal quiet Internal quiet he established by strictly applying such laws as existed against those who should break the peace; and the robber nobles never found a more implacable enemy. The cities flourished during his reign, and he attached them to himself by granting to many of them the very liberties which, by a too literal interpretation of his imperial rights, he withheld from the cities of Lombardy. Yet, with all this, the nobles appear to have been enthusiastically devoted to him. They followed him time after time into Italy,

going through incredible sufferings that he might assert claims which were of no advantage to them, and which had been a curse to their nation. On one occasion, when a too confident legate read before the diet a papal letter, which seemed to imply that the empire was a fief of the papacy, indignant murmurs broke from the assembly, and the life of the offender was saved only by the intervention of Frederick himself. The secret of this great popularity was partly the national pride excited by his foreign achievements, partly the ascendancy which his genius gave him over other minds, partly the conviction that, while he would abate nothing of his rights, he would ask no more than the laws of the empire sanctioned.

In the later years of Frederick's reign, Henry the Lion ^{the Lion.} had the misfortune to incur his deep displeasure. The duke, rendered arrogant by success, positively refused, because his conditions were not admitted, to attend the emperor in the Italian campaign which resulted in the fatal battle of Legnano. Ascribing this defeat wholly to Henry, Frederick returned to Germany resolved to work his ruin. Summoned on three different occasions to attend the diet, Henry held aloof; whereupon, by judgment of his peers, he was condemned to the loss of both his duchies. After some resistance he submitted; but the utmost favour he could secure was permission to retain Brunswick and Lüneburg, while his term of banishment to England was reduced from seven years to three. Bavaria was granted to Otto of Wittelsbach, but it lost much of its importance, for, among other changes, Styria was taken from it and made a separate duchy. Saxony was finally broken up. The duchy was confined to a comparatively small territory to the east of Brunswick and Lüneburg, and conferred upon Bernard, son of Albert the Bear, while most of the western half of the country was attached, as the duchy of Westphalia, to the archbishopric of Cologne. The chief prelates of Saxony, and many of the most important vassals of the duke, such as the counts of Oldenburg, of Holstein, and of Schwerin, were made virtually independent of all control save that of the crown. Frederick's object in thus disintegrating the two greatest duchies in the kingdom was, by playing off the nobles against each other, to secure imperial authority. But, in reality, he made it doubly certain that the princes would one day shake off imperial power altogether; for it was incomparably more difficult for the sovereign to contend with scores of petty nobles than with two or three great lords.

Towards the close of Frederick's career fortune appeared ^{years of} to smile upon him. (Germany was at peace; even in Italy, since the force of events had persuaded him that the time was past for too severe a straining of his lawful claims, he had been well received by the cities which had wrought him so much disaster; pope and emperor were temporarily reconciled; and, by the marriage of his son Henry with the princess Constantia, he had reason to hope that the empire would soon include Naples and Sicily. Resolving that the sunset of his life should be even more splendid than its dawn, he undertook the third crusade, and started with a great army for the Holy Land. When the news reached Germany that he had been drowned, men felt that evil days must come, since the elements of strife could no longer be controlled by his strong hand.

Evil days did not, however, come in the time of Henry Henry VI. (1190-97), who, although without his father's greatness of soul, had his determination and energy. Partly by means of the immense ransom obtained from his prisoner Richard of England, he was able to beat down resistance in the south Italian kingdom to which his marriage entitled him; and the papacy was more completely subject to him than it had ever been to Frederick. In Germany he was so powerful that he not only secured the election of

his infant son Frederick as king of the Romans (as a king elected during the lifetime of an emperor was now and henceforth called), but he made proposals that the crown should be declared hereditary. To secure this important end, he offered so many concessions that, but for his sudden death, it would probably have been achieved.

Great as was Henry's authority, there had been a dangerous conspiracy against even him, and after his death the princes who had taken part in it refused to recognize his son. There was now a double election, those who were favourable to the Hohenstaufen dynasty choosing Philip, Henry's brother, their enemies appointing Otto, son of Henry the Lion. Had Germany had no relation to the papacy, or had the papacy continued as weak as in the days of Henry VI., there could have been no doubt how the strife would end. A large majority of the princes were on Philip's side, and his personal character commanded universal respect, while Otto was a man without principle, harsh and violent. But, to Germany's misfortune, the papal see was at this time held by Innocent III., a pope in whom were revived the ambition, statesmanship, and force of Hildebrand. After a little delay he decided for Otto, and thenceforward for some years the country was desolated by civil war. Even with the help of the pope, Otto by and by lost ground, and Philip, had he not been murdered, in 1208, would soon have been universally acknowledged. After his death, however, there was no longer any excuse for war, and Otto IV. was crowned emperor. While his position was undecided he remained a humble suppliant of the pope, but after his coronation he cast aside his pledges, and began to act as an independent sovereign. Up to this time Frederick, the son of Henry VI., had lived in his southern kingdom, nominally under the guardianship of Innocent, but in reality left to be trained by the severe discipline of practical life. Although the pope did not altogether like him, he now resolved to punish Otto by bringing forward this young prince as a candidate for the German throne. A party among the princes was easily induced to elect him, and in 1214 he started, full of youthful hope, on his journey across the Alps. In the period which followed, he displayed an unsurpassed power of managing men; while Otto, thinking to injure him by indirectly striking a heavy blow at his patron the pope, was short-sighted enough to leave Germany and to support John of England against the French king, Philip Augustus. In the battle of Bouvines, memorable alike in the history of England, France, and Germany, his fate was sealed. After so crushing a defeat nothing remained for him but to make way for his rival by withdrawing from public life.

Frederick II. (1212-50), if not the strongest, was personally the most brilliant, of the German kings. With the medieval passion for adventure he combined the intellectual freedom and culture of a modern gentleman. A lover of poetry, of science, and of art, he was also a great statesman; with a power of will which the most adverse circumstances could not break, he knew how to adapt his policy to changing circumstances, and how to move men by appealing at one time to their selfishness and weakness, at another to the most ideal qualities of human nature. And for outward splendour his position never was surpassed, since, when he died, he possessed no fewer than six crowns,—the imperial crown, and the crowns of Germany, Burgundy, Lombardy, Sicily, and Jerusalem. But Germany, his proper kingdom, profited not at all by his magnificent gifts. In 1220 he left it for a space of 15 years, to accomplish his famous crusade, to carry on his bitter contest with the Lombard cities and Pope Gregory IX., and to rule Sicily, with an insight into its needs that made it the most prosperous land in Christendom. In his absence he was represented in Germany by his young son Henry, who was

crowned king of the Romans, and in whose name the 1190-1250 country was governed by two successive regents. Through-out the kingdom the princes did very much what seemed good in their own eyes; and in the north a confused warfare was carried on between the Germans and the Danes. As there was now no powerful Saxon duke to uphold the northern interests of the kingdom, and as the central Government did not choose, or was unable, to act with energy, the Danes had decidedly the best of this struggle, and extended their power along the Baltic coast. At the same time Prussia was conquered for Christianity and for civilization by the knights of the Teutonic Order, who here slowly built up the state which ultimately, in association with Brandenburg, was to influence so profoundly the course of history. Crusading knights from all lands came to their help against the Prussian heathen, and their strength was permanently increased by their union with the Knights of the Sword, who, before their appearance in Prussia, had been subduing Livonia and Courland. In all these countries Christian institutions were introduced, and German settlers brought with them the peaceful arts.

As young King Henry grew up, he displayed none of the good characteristics of his house, and in 1236 he openly rebelled. So confident was Frederick of his own position that he entered Germany with only a few personal attendants, and his presence had the effect he anticipated. At Mainz, amid circumstances of unprecedented pomp, he held a diet which was attended by nearly all the princes, and Henry was solemnly deposed. Yet Frederick was in reality watched with sullen suspicion. The princes did not know what might be implied in his extraordinary display of imperial power; they resented his evident dislike of their country, as loyal sons of the church, they could not but hold somewhat aloof from one who was believed to be at heart a Mahometan. It was significant of the limits of his influence that, in declaring private war to be unlawful, he had to except cases in which justice could not be obtained; and that, although desirous of setting up courts of justice which should make private war unnecessary, he could only establish a tribunal from whose jurisdiction princes of the empire were excluded.

Some years after this, the gulf between Frederick and the nation was further widened by his indifference to the fearful danger by which Germany was threatened. Hordes of Mongols appeared on the eastern frontiers, yet Frederick had neither counsel nor help for his subjects; the peril was ward off independently of him by the brave margrave, Henry of Liegnitz. At that time he was once more absorbed by his Italian wars. In Innocent IV. he found an enemy quite as persistent as Gregory IX. Innocent grasped at the old and well-tried weapon, the ambition of the princes; and he succeeded so far as to induce a number of them, mostly prelates, to accept his sentence of deposition, and to appoint a rival king. The king of their choice was Henry Raspe, landgrave of Thuringia, a rude noble, who had extended his territories at the expense of those of his dead brother, husband of the famous St Elizabeth of Hungary. Frederick's younger son, Conrad, who had some time before been elected king of the Romans, resisted the parsons' king, as Henry Raspe was popularly called; and the rebellion did not at any time assume dangerous proportions. After Henry Raspe's death, the papal party elected William, count of Holland, a prince who had no quality to recommend him, except that he was young and weak, and therefore likely to be a willing tool in the hands of his friends. Had Frederick chosen to leave the Lombard cities, he might still have found sources of strength in Germany; but he preferred to remain at what he considered the centre of his empire, and King Conrad had no influence enough to restore harmony. At the time of the emperor's death, when he was almost ready

1250-54. to make a new spring at his enemies, but when to the world he seemed to have lost everything, the prospects of his supporters were dark indeed. They acknowledged Conrad IV. as their lawful sovereign, but he, too, fought in Italy rather than at home, and the country continued till his death, in 1254, to be torn by the two contending factions.

With King Conrad IV. the Hohenstaufen line came to an end in Germany, and William of Holland received a nominal allegiance. In two years he followed his predecessors, and then there was a double election, that of Alphonso, king of Castile, and Richard, earl of Cornwall, brother of Henry III. of England. Richard was crowned, but he went to Germany only three times, and the majority of his subjects probably hardly knew his name. Alphonso never even visited the country of which he also claimed to be the sovereign.

Period of
Hohen-
staufen
dynasty.

The age of the Hohenstaufen emperors is, in many respects, the most interesting in the mediæval history of Germany. Everywhere there were dramatic contrasts of character: in the innumerable struggles of the time we are struck, now by heroic devotion, again by almost incredible selfishness, a gay enjoyment of the world as it is existed side by side with almost superhuman spirituality. Chivalry was in full bloom, with much in its nature that was fantastic and insincere, but keeping alive a beautiful ideal of manliness, courtesy, and generosity. Women never held a higher place, nor, on the whole, did they ever respond more nobly to the honours freely lavished upon them. The excitement of the crusades, contact with the life of Italy (in that age presenting so many elements fitted to awaken even dull minds), and study of the Provençal poets revealed worlds that had been hitherto unknown; while the national genius for the first time flowered in the romances and lyrics of the Minnesänger. In the cities, magnificent churches in the Gothic style gave expression to high aspiration, and gratified a cultivated feeling for art. And the problems of government were seen in new lights, partly from the study of Roman law which passed from Italy to Germany, partly from the summaries of native custom in the "Sachsenspiegel" and "Schwabenspiegel." Altogether, Germany has seen no more fascinating epoch, none more full of life, movement, and colour.

Political
character
of
Germany
settled.

Yet it was in this age that the German nation utterly lost its political strength. Even after Lothar the Saxon, of a line of sovereigns rigidly confining themselves to their own kingdom might have mastered the many influences which were making for disunion. But the Hohenstaufen family, like their Saxon and Franconian predecessors, would be content with nothing short of world-dominion; and thus the crown which had once been significant of power and splendour gradually sank into contempt. Under the strong rule of Frederick Barbarossa and his son the process was temporarily stopped, but only to advance the more rapidly when they were gone. During the confusion of the civil war carried on by Otto IV. and Philip, the princes, being subject to hardly any check, seized crown lands and crown rights; and the mischief was too extensive to be undone by Frederick II. In 1220, in order to secure the adhesion of the church to his son Henry, he formally confirmed the spiritual princes in their usurpations, agreeing not to introduce into their territories, without their consent, new coinage, or customs, or tolls. Fifteen years later the rebel king, Henry, was isolated by similar advantages being granted to the secular princes. The two pragmatic sanctions in which Frederick made these concessions formed the lawful basis of the independence of the princely class. Such authority as he reserved he could ill exercise from a distant land in which his energies were otherwise occupied. His immediate successors can hardly be said to have exercised any authority whatever; and they lost hold of the

border countries which had hitherto been dependent upon or connected with Germany. Denmark and Poland rendered no homage thenceforth to the German crown, and Burgundy was gradually absorbed by France.

The country was now not divided into a few duchies ^{Classes} which, with skilful management, might still on difficult of the emergencies have been made to act together. The age of the great duchies was past. As we have seen, Bavaria was shorn of extensive lands, over which new dukes were placed, and the duchy of Saxony was altogether broken up. Swabia and Franconia also ceased to have dukes, and Lorraine gave place to the duchy of Brabant and other small immediate states. Thus there were prelates, dukes, palatine-graves, margraves, landgraves, counts—forming together a large body—each of whom claimed to have no superior save the emperor, whose authority they and their predecessors had slowly destroyed. All immediate nobles were not princes; but even petty knights or barons, who possessed little more than the rude towers from which they descended upon passing travellers, if their only lord was the emperor, recognized no law save their own will. Another independent element of the state was composed of the imperial cities. So long as the emperor really reigned, they enjoyed only such liberties as they could wring from him, or as he voluntarily conferred. But when the sovereign's power decayed, the imperial cities were really free republics, governing themselves according to their own ideas of law and justice. Besides the imperial cities, and the princes and other immediate nobles, there were the mediæval nobles, the men who held land in fief of the highest classes of the aristocracy, and who, in virtue of this feudal relation, thought themselves entitled to look down upon allodial proprietors or freemen, and upon simple burghers. There were also mediæval towns, acknowledging the supremacy of some lord other than the sovereign. Beneath all these, forming the mass of the agricultural population, were the peasantry and the serfs, the latter attached to the land, the former ground down by heavy taxes.

The period which followed the death of Conrad IV., called ^{Great} the Great Interregnum, was made good use of by the princes ^{interregnum} for the extension of their territories and the confirmation of their authority. On several occasions the crown had ^{electors} seemed to be on the verge of becoming hereditary; but the jealousy of the papacy, and the growing influence of the aristocracy, had succeeded in keeping it elective. Although each election needed the sanction of the whole class of immediate nobles, the right of appointing the king had long been virtually in the hands of the leading princes. During the interregnum, mainly through the influence of Pope Urban IV., it was definitely transferred to the archbishops of Mainz, Cologne, and Treves, the houses of Wittelsbach and Saxony, the margrave of Brandenburg, and the king of Bohemia. After this the electors became a distinct element in the state. Their importance consisted in this, that they could maintain the existing disunion by imposing rigid conditions on candidates for the crown, and by taking care that it should be conferred on no prince likely to be dangerous to the aristocracy.

Up to the time of the interregnum the territories of a ^{prince} prince were never divided among his descendants, the reason of ^{princes} being that, although the private fiefs of the princes were ^{Palatinate} hereditary, their offices as rulers were in theory at the disposal of the crown. This principle was now set aside. Otto, duke of Bavaria, of the house of Wittelsbach, had become by marriage lord also of the Rhenish palatinate. After his death these extensive lands were ruled in common by his two sons; but a formal division soon took place, by which the powerful family of Wittelsbach was separated into two branches, the Palatine and the Bavarian. The small duchy of Saxony was also divided into two duchies,

that of Wittenberg and that of Lauenburg, the former to the south, the latter to the north, of the great march of Brandenburg. About the same time there were like divisions in Nassau, Brunswick, Meissen, and Holstein. It was thus practically settled that the offices and territories, as well as the private fiefs, of the princes were hereditary, to be disposed of by them at their pleasure. This being thoroughly established, it would have been hard, perhaps impossible, even for a sovereign of the highest genius, to reassert in anything like its full extent the royal authority. The process of division and subdivision which steadily went on broke up Germany into a bewildering multitude of principalities; but as a rule the members of each princely house held together against common enemies. Ultimately they learned to arrange by private treaties that no territory should pass from the family while a single representative of it survived.

This consolidation of the power of the princes was contemporary with the rise of the cities into new importance. The destruction of imperial authority compelled them to organize their resources, so as to be at all times prepared against ambitious neighbours. They began to form leagues, which the greatest princes, and combinations of princes, could not afford to dispense. Of these leagues the chief at this time was the Rhenish Confederation, which was founded by Mainz and Worms, and which, within a year of its formation—so pressing was the need of union—included about 70 cities,—among them Cologne, Strasburg, Basel, and towns far to the east and north, such as Nuremberg, Erfurt, and Bremen. Great importance was also acquired by the Hanseatic League, which had originated some time before the interregnum in a treaty of alliance between Lubek and Hamburg. It ultimately included more than 80 cities, and became one of the greatest commercial powers in Europe.

A political system which allowed the princes to do as they pleased was exactly to their liking; and had they been able to follow their own impulses, it is improbable that they would have placed over the country even a nominal king. But the papacy intervened. It found in its troubles at home and from its diminished northern revenues that it would still be convenient to have in Germany a sovereign who would, like his predecessors, be the protector of the church. Pope Gregory X, therefore, after the death of Richard, let the electors know that if they did not choose a king he himself would appoint one. This threat was effective. The electors met, and raised to the throne

Rudolf II, count of Hapsburg, a petty Swabian noble who was supposed to be too unimportant to do much harm. Rudolf (1273-81), however, proved himself to have much more energy than the dictators supposed. For a long time the most powerful prince in Germany had been Otocar, king of Bohemia. He had by marriage and conquest obtained a great territory beyond his native state, including the Austrian possessions of the house of Babenberg, of which the male line had died out. As he had himself expected to receive the German crown, he refused to do homage to the new sovereign, who could not for a time compel his allegiance. At last, in a great battle at the Marchfeld, Otocar was defeated and slain. Rudolf has often been called the restorer of the German kingdom, but he has no real claim to this honorable title. In the later years of his life he made some attempts to maintain the public peace, and he distinguished himself by the vigour with which he punished robber barons; he also won back some of the crown lands and dues which had been stolen during the interregnum. But he made no essential change in the condition of Germany. There was but one way in which a king could hope still to overcome the arrogance of the princes, and that was to encourage the cities and to form with them a close and enduring alliance. This was the

policy pursued by the French kings, and it was pursued with splendid effect. But Radolf invariably favoured the princes rather than the cities. The latter had a peculiar class of citizens called "pfälbürger," who dwelt in the open country beyond the city palisades, and could claim the protection of the city authorities. As freemen were able, by becoming pfälbürger, to escape from the tyranny of local despots, the princes vehemently opposed the right of the towns to receive them. Radolf not only took the side of despotism in this important struggle, but harassed and weakened the cities by subjecting them to severe imposts. He had all the sympathies and prejudices of a noble; and the supreme object of his life was not to increase the authority of the state, but to add to the greatness of his own family. In this he was brilliantly successful. Some years after the fall of Ottocar he obtained the assent of the princes, notwithstanding their dislike of the scheme, to the granting of Austria, Styria, and Carinthia in fief to his son Albert. Carinthia was given to Meinhard, count of Tyrol, on condition that on the dying bed of his male line it should fall to Radolf's descendants. Thus Radolf made himself memorable as the founder of the house of Hapsburg, which from his time formed one of the most influential forces in the national life of Germany.

In vain Rudolf sought to obtain the crown for his son; the electors would not take a step that might endanger their special rights. Guided mainly by the archbishop of Cologne, they chose Adolf, count of Nassau (1291-98), a noble of even less importance than Rudolf had been. He had, however, a considerable reputation for valour and ability. Edward I. of England persuaded him to form an alliance against France. Instead of applying the large sum sent from England to promote the objects of the alliance, Adolf was unprincipled enough to expend it in the purchase of Tübingen from the worthless landgrave, Albert the Degenerate. As the transfer was resisted by Albert's sons, it led to a war in which Adolf was opposed by several princes. In his general policy he was much more enlightened than in these wretched proceedings, for he detected what had escaped his predecessor, the value of the cities as the true support of the monarchy. He relieved them of some of their burdens, and upheld them in the controversy respecting the pfälzgräve. Taking alarm, the electors met, and by an irregular vote proclaimed him dethroned. Adolf resisted, but lost his life in a battle near Worms.

Now that there could be no pretext for asserting that the Albert I. crown had been obtained by inheritance, Duke Albert of Austria, Rudolf's son, was chosen to be Adolf's successor. Albert I. (1298-1308), like his father, made it his principal object to extend the power of his house, and he came very near to securing Bohemia and Thuringia; but his schemes were cut short by a violent death. Although a hard, stern man, he had a keen sense of justice when his selfish interests were not involved, and few of the German kings possessed so strongly practical an intelligence. He encouraged the cities even more effectually than his predecessor, and was not content with issuing proclamations against private war, but formed alliances with the princes in order to enforce his decrees. The serfs, whose wrongs seldom attracted notice in an age indifferent to human dignity, found a friend in this severe monarch, and he protected even the despised and persecuted Jews.

Albert's successor was Henry, count of Luxembourg. Henry VII. (1308-13) was fortunate enough to obtain for his son John the crown of Bohemia, but the aggrandisement of his family was not the main object of this remarkable sovereign, the last of the German kings of the old, grandly ambitious type. It was the memory of the empire which stirred his blood; and from the beginning of his reign he looked forward to the assumption of the Lombard and

1308-47, imperial crowns. His purpose of crossing the Alps at the head of a mighty force was hailed with delight in Italy by the Ghibelline faction, whose aspirations found noble utterance in Dante's prose; but the emperor lived too short a time to fulfil the hopes of his friends. The effect of the connexion of Germany with the empire was in his time, as in former ages, altogether mischievous; for before starting for Rome he tried to conciliate the princes by adding to their already enormous privileges and by repressing the enmities of the cities.

Frederick III and Louis IV. The electors, with their usual dread of the crown becoming hereditary, would not appoint Henry's son, John, the young king of Bohemia. But they were unable to agree on any one else, and the result of their disputes was a double election—one party choosing Frederick the Fair, duke of Austria, son of Albert I.; another, Louis, duke of Bavaria. War at once broke out and lasted for about nine years. In 1332 the rival claims were set at rest by the battle of Mühldorf, in which Frederick's army was decisively routed. Louis had no personal ill-will to his opponent, who was the friend of his youth; and in 1335 he agreed that they should rule in common. Frederick III., however, being without strength of character, sank into insignificance, and in 1330 he died.

The success of Louis IV. (1314-47) in the war with Frederick was to a large extent due to the imperial cities, which clung to him from the first. They not only willingly paid high taxes, but made splendid voluntary contributions; and they often stimulated anew the king of their choice, when he himself would have preferred to give up a struggle in which the sympathies of most of the princes and nobles were with his enemy. He was even more indebted to the memorable conflict between the house of Hapsburg and the League composed of Schwyz, Uri, and Unterwalden. The inhabitants of these districts claimed to have never owed allegiance to any sovereign save the emperor. Although this claim had been confirmed by King Adolf and Henry VII., the dukes of Austria would not recognize it, and when Frederick was chosen king by his party among the electors, he sent bailiffs into the country to bring it under the rule of his family. Probably the tyranny of these officers, although it occurred at a later time than that to which the Tell legend refers, afterwards gave rise to the romantic tales which gathered around the name of the mythical champion of Swiss independence. At any rate it brought on a conflict between Austria and the confederates, which strained the resources of Frederick at the very time when he needed them in defence of his royal claims. It was not only Louis who profited by this struggle, for the splendid battle of Morgarten Pass laid the foundation of the structure which we now see in free Switzerland.

Had Louis been a wise prince it would have been easy for him to rise to a great position after the battle of Mühldorf; but he was wayward, treacherous, and selfish. He mortally offended King John of Bohemia, who had been of great service to him, but who now became his bitter and unrelenting enemy. Pope John XXII., stirred up by Charles IV. of France, who had some hope of obtaining the empire for himself, took advantage of the strife of the two princes, and arrogantly claimed that the German crown could not be worn but with papal sanction. When Louis gave the answer that was to be expected, the pope responded by excommunicating him and by placing under the interdict all places by which he should be supported. Thus it seemed that the ancient struggle between the papacy and the empire was to be revived; but the pope and his French master had altogether misread the signs of the times. The princes had no longer, as in former ages, reason to dread an ambitious ruler; the kingdom was their own, and therefore they could not tolerate that its destinies should be

decided by a foreign power. Even the spiritual princes for the most part took this view. The electors had of course the strongest of all motives for resisting the papal claim, since, had it been conceded, they would have been deprived of their importance. As for the cities, they had stood beside the empire in the most difficult crises of its contest with Rome, and they were not likely to desert it now. Encouraged, or rather driven forward, by the national sentiment, Louis continued to maintain the independence of his crown, and even made a descent upon Italy, where he was crowned emperor by his own anti-pope. This enterprise ended disastrously, but it made no difference in the conditions of the controversy. Louis was personally very much frightened by the possible consequences of excommunication, and intrigued incessantly with Pope John and his successor Benedict XII. to be taken back into the church. In order to win papal favour he basely betrayed Edward III. of England, with whom he had formed an alliance against the French king, Philip VI. The nation, however, stood fast, and in 1338 the electors, with the exception of King John of Bohemia, met at Rense, near Coblenz, and formally declared that the German king and emperor, if appointed by a majority of the electors, received his authority from God alone, and needed not papal sanction in the exercise of his rights. This declaration was accepted as the fundamental law of the empire by a diet which Louis summoned in Frankfort, and which was largely attended by princes, nobles, and citizens.

Louis did not maintain the popularity forced upon him by this conflict. His greed of territory for his family made him so unscrupulous, and excited so many jealousies, that the Bohemian king succeeded in forming a party against him; and in 1346 a number of the electors voted his deposition, and appointed in his place Charles, margrave of Moravia, King John's son. The cities persisted in their loyalty, and few of the princes were willing to involve themselves in another great war; so that for a time the sentence of deposition had no effect. But after King John had met his death, fighting heroically despite his blindness as the French king's ally, on the field of Crécy, Charles, who succeeded him on the Bohemian throne, began to make vigorous preparations; and probably the sudden death of Louis prevented Germany from being once more rent by civil strife.

Notwithstanding the defects of Louis's personal character his reign was one of the most important in German history. The claim of the papacy to political supremacy received in his time its deathblow, and the popes themselves sowed the seeds of the spiritual alienation from Rome which was effected at the Reformation. In regard to the public peace, Louis persistently followed the lines laid down by Albert I. He encouraged the princes to form alliances for its maintenance, and at the time of his death such alliances existed in all parts of the country. To the cities he usually showed Louis IV. himself a faithful friend. In many of them there had been and there still is for more than a century a struggle between the old patrician families and the guilds composed of workmen and tradespeople. Louis could not always follow his own impulses; but whenever he could, he associated himself with the latter party. Thus in his day the government of the imperial cities became more democratic, and industry and trade flourished as they had never before done. The steady dislike of the princes was the best proof of the importance of the cities. They contained elements capable of enormous development; and had a great king arisen he might even yet, by their means, have secured for Germany a truly national life.

The friends of Louis elected Günther, count of Schwarzburg, but Charles IV. (1347-78), by a liberal use of bribes, bought over his enemies; and Günther himself resigned

IV.

his claim, and soon afterwards died. Charles was an accomplished diplomatist, of a keen and penetrating intellect, but capable of almost any treachery in order to gain his ends. Apparently the most pliant of men, he had in reality great persistence of character, and if foiled in one set of plans readily turned round and reached his goal by a wholly different path. The result of his endless intrigues was that, when he died, he wore the crowns of Bohemia, of Germany, of Burgundy, of Lombardy, and of the empire; and he succeeded in adding to his native kingdom Lusatia, Silesia, and Brandenburg. As a Bohemian king he ranked high among the rulers of his day. He so carefully organized the administration, and practised such strict economy in government, that no German country was so lightly taxed as Bohemia, and it became, under his rule, a home of learning and of the arts. Towards Germany he was cynically indifferent, caring for it only in so far as it could add to his personal welfare. It never stood in more urgent need of a strong and beneficent ruler than in the early years of his reign, for the Black Death swept over the land, and the half-mad population rose in fury against the Jews, who were supposed to have in some way caused the evil. In dealing with this monstrous outbreak of fanaticism, many of the princes, both spiritual and secular, displayed vigour and humanity; but Charles saw in the suffering of the down-trodden race, which was peculiarly under his protection, only an excuse for robbing it of its wealth.

Golden
Bull.

His most famous achievement is the Golden Bull. Although the principle of election to the crown had long been settled, it was surrounded by many practical difficulties. It had never, for instance, been decided whether all the princes of each electoral house were entitled to vote; nor was it certain, when a choice was made among several branches of a family, by what law the choice ought to be regulated. The Golden Bull, which was granted as the result of many tedious negotiations in 1356, was primarily intended to set at rest such doubts as these; but it did very much more. It decided that the number of electors should be strictly limited to seven, that the spiritual electors should belong as before to the archbishops of Mainz, of Cologne, and of Treves, and the secular electors to the king of Bohemia, the Rhemish palgrave, the duke of Saxony (Sachsen-Wittenberg), and the margrave of Brandenburg. That there might be no possibility of dispute between the princes of a single house, these countries were declared to be indivisible, and to be heritable only on the principle of primogeniture. The electors were invested with full sovereign rights within their territories, and their subjects were allowed to appeal to the royal or imperial tribunals only if the administration of justice should be refused. The king of Bohemia received precedence among the secular electors, but it is difficult to believe that this alone was his aim in making these vast concessions. Whatever may have been his motives, the effect of the Golden Bull was to perpetuate the disunion of the state. With such powers the electors collectively were of more importance than the sovereign; and their greatness stimulated the other princes to seize every chance of acquiring like privileges.

Fehm-
gericht.

If we except the Golden Bull, the true interest of Charles's reign is not in his unimportant labours for Germany, but in the movements beyond the range of his influence. It is significant that at this time the Fehmgericht, for whose origin we must go back to the 12th century, vastly extended the sphere of their activity, and that in the utter absence of central authority they were respected as a rough check upon the lawlessness even of high princes. The cities, notwithstanding every kind of discouragement, formed new associations for mutual defence, or strengthened those which already existed. The Hanseatic League carried

on war with the Danish king and forced him to come to 1347-terms, and its commerce was extended to nearly every part of the known world. A powerful league was formed by the Swabian towns, but it was defeated in the battle of Alheim by a confederation of princes who regarded its growth with fear and jealousy.

Wenceslaus (1378-1400), son of Charles IV., and also Wenceslaus king of Bohemia, had some good natural qualities; but ^{lous} he had been badly trained, and when he became his own master was indolent and capricious. His bloodhounds had stronger attractions for him than the duties of government, and even more than his father he left Germany to look after itself. The tendency to association became the deepest of the time; princes allied themselves against cities, cities against princes, and nobles against both. For a brief period the prospects of the cities seemed to be splendid, for the Swabian League recovered from the effects of its reverse, extended its relations far and wide, and formed an alliance with the Swiss confederates. The latter won the brilliant victories of Sempach and Nafele, and had the Swabian League taken advantage of the opportunity, it might have definitely gained predominance. But it gave the princes time to reorganize their scattered forces, and in 1388, in the battle of Duffingen, it suffered complete defeat. So crushing was this blow that the Swabian cities were never again so strong, and all over Germany it encouraged the princes to fresh aggression.

The confusion caused by the king's neglect of his most elementary duties gave rise to a conspiracy against him, in which Rupert, the elector of the palatinate, took a leading part. Wenceslaus was deposed, and after much intrigue the crown was granted to Rupert (1400-10). He was an excellent elector, and under favourable circumstances would have been a good king; but such were the jealousies and divisions of the state that he found no scope for his energy beyond his native dominions. He made an attempt to reach Rome, but the result covered him with ridicule. After his death Jobst, margrave of Moravia, and Sigismund, king of Hungary, brother of Wenceslaus, were elected by opposing parties. Jobst soon died, and then Sigismund was generally recognized. Sigismund (1410-37) was an intelligent and cultivated prince, but vain, restless, and shifty. He could mind-form great plans, but had not determination to execute them, and was easily moved by flattering counsellors. The commanding questions of his reign were ecclesiastical. It was the age of the great schism, and through all ranks of the church there was an urgent cry for thorough reform. Unfortunately, the council of Constance, summoned mainly through the efforts of Sigismund, marred its labours by the judicial murder of Huss and Jerome of Prague. This atrocious act, for which the king was to a large extent responsible, stirred vehement rage among the Bohemians; and when, after the death of Wenceslaus, Sigismund, as his heir, claimed the crown, they broke into revolt. Led for a time Hussite by the blind general Ziska, and afterwards by commanders ^{war} who, although his inferiors in genius, were of equally resolute temper, they defeated army after army, and spread havoc through the neighbouring German lands. So divided was Germany, and so poor was Sigismund himself, that for fifteen years he could not collect a force sufficient to put down the rebellion; and he at last succeeded only because the Hussites gradually split into two factions, the Calixtines and Taborites, and he was able to conciliate the less extreme party.

Sigismund, who was of lavish habits, never had enough ^{Branden-}money for his wants; sometimes he had even to force ^{burg} himself upon princes and cities as an unwelcome guest. This undignified poverty had one good result. In return for 400,000 gulden he granted to his friend Frederick, count of Hohenzollern, first as a pledge, afterwards as a permanent

Hapsburg dynasty Albert II. Sigismund was succeeded by Albert, duke of Austria, who, as his son-in-law, became king of Bohemia and Hungary. Although the German crown remained elective, it was henceforth always conferred on a member of the house of Hapsburg until the extinction of the male line; and the same family never willingly lost its grip of the two countries which now fell to it, and of which it ultimately gained complete possession. Albert II. (1438-39) evidently meant well by Germany; but his reign was too short to enable him to do more than indicate his good intentions. He was succeeded by Frederick, duke of Styria.

Frederick IV. (1440-93), unfortunately for his subjects, occupied the throne longer than any other sovereign. He was a solemn trifler, obstinate without being firm, and bent on promoting only the interests of his family. The council of Basel having met after the council of Constance, King Albert accepted its reforming decrees, and it appeared probable that the abuses which scandalized Christendom were about to be brought to an end. But Frederick, whose dull mind did not see that in the changed circumstances of the world the papacy could be strong only in proportion to its purity, fancied that in its existing condition it might be made a powerful ally of the empire. He accordingly carried his subservience so far as to sign in 1448 the concordat of Aschaffenburg, perpetuating the very evils from which the church had aimed at delivering itself. After his assent had been obtained it was comparatively easy to overcome the scruples of the princes, so that the chances of a voluntary reformation were lost; the upheaval of the 16th century was rendered inevitable.

Frederick's career is one of great importance in Austrian history; he was involved in wars with the Turks, with the Hungarians, with his brothers, and with his own subjects. In 1462 he was crowned emperor, being the last who passed through the ceremony in Rome. He had no influence in Italy; and in Burgundy he could neither check the towering ambition of Charles the Bold, nor after Charles's death prevent the seizure of the duchy of Burgundy by the French king. In Germany he hardly made a pretence of exercising supreme authority, and many private wars were waged, especially between the cities and the princes. The most famous of those was the margraves' war, carried on by Albert of Brandenburg with a number of princely allies against Nuremberg, which had the support of the Swiss League and upwards of 70 cities. The war was in every respect a critical one. Had the cities gained they might still have aimed at balancing the power of the princes; but owing partly to their imperfect union, partly to the necessity of fighting with hired troops, they were not successful. They won, indeed, great advantages in the course of the war; but after the conclusion of peace it was felt that on the whole they had decidedly lost ground. After this struggle, which lasted seven years, there could be no doubt as to the element in which the centre of gravity of the state was to be found.

Local diets. The princes, however, did not have everything their own way. About this time their power was seriously limited by the formation of diets in nearly all the principalities. These bodies were composed of the mediate prelates, the mediate nobles, and representatives of the mediate cities. They were not summoned because the princes wished their aid, but because arms could be had only with the consent of the nobles, and money only with that of the cities and the clergy. When once formed, the local diets soon extended their functions. They claimed the right of sanctioning taxation; they had something to say as to the expenditure of the public revenues; they insisted on

justice being administered. Such institutions as these were clearly of the highest importance, and for two centuries they did much to make up for the lack of a genuine monarchy.

During this reign the conditions of warfare began to be radically changed. The discovery of gunpowder made small bodies of men, properly armed, more than a match for great forces equipped in the mediæval style. Hence the custom of hiring mercenary troops came into use; and a prince could never feel sure, however numerous his vassals, that the advantage would not rest with his opponent. This fact, added to the influence of the local diets, made even the princes sick of war; and everywhere a demand arose for the reform of the national institutions. In 1488 a great Swabian confederation, consisting of princes, nobles, and towns, was created for the establishment of peace; and its effects were excellent. But obviously no partial remedy of this kind could suffice; it was essential that there should be some central reform by which every part of the kingdom could be effectually reached. Had the proposal been that the imperial authority should be directly strengthened, Frederick would not have objected; but the scheme repeatedly forced upon him was that he should in some form delegate to others the power which theoretically belonged to him, so that it might really be put in force. The emperor doggedly withheld his assent, and the nation impatiently waited in the hope that his successor would be more pliant.

Maximilian I. (1493-1519) mounted the throne with unusual advantages. He was not only lord of the greater Austrian lands, but, as husband of the princess Mary, daughter of Charles the Bold, administered the Low Countries and the free county of Burgundy. These territories he soon gave up to their lawful ruler, his son Philip; but the fact that they were in the possession of his family added to his influence, which was still further increased when Philip, by marrying the infant Joanna, had the prospect of becoming king of Spain. From this time the empire exercised in the affairs of Europe an authority which had not belonged to it for several centuries. The reason was not that the empire itself was stronger, but that the crown was held by princes who were in their own right mighty sovereigns.

This emperor is often called the last of the knights, and in some respects the name is strikingly appropriate. He had not, indeed, sufficient dignity to rank among the greatest representatives of chivalry. A knight who was also emperor ought not, for instance, as Maximilian did at the siege of Tournonne, to have received a foreign prince for pay. But he possessed many of the more prominent qualities suggested by the word chivalry; he was a man of fascinating manner, a lover of poetry and art, and endowed with a bold and adventurous spirit. Above all, he was a knight in his political opinions. Maximilian never could learn that the world had changed since the time of the Hohenstaufen dynasty; that the old order of society was passing away, and a new order arising, was altogether hidden from him. An irresistible fascination attracted him to the glitter of the mediæval empire, and the best part of his life he spent in vague schemes for its revival. The agitation for reform in the direction indicated by the princes and the cities met his unqualified disapproval. During the whole course of his reign the diet, which was now composed of three colleges, the electors, the princes, and representatives of the imperial cities, urged him with even greater importunity than it had displayed toward his father, to adapt himself to the circumstances of the time. The only occasions on which it could bend him to its will were when he needed money for his military enterprises; and by taking advantage of these opportunities it obtained his sanction to the division of the

kingdom into ten circles, each with its own administrators, appointed for the purpose of preventing private war. These institutions were of genuine service, but no other real concession could be wrung from Maximilian. In his first diet, held at Worms in 1495, a permanent public peace was proclaimed, and he unwillingly consented to the formation of an imperial chamber, consisting of a president and assessors, the former to be appointed by the emperor, the latter by the states. This chamber was to judge between princes of the empire, and to act as a court of appeal for parties of lower grade, and partly for the payment of its expenses a tax called the common penny was granted. Maximilian, who was always in straits for money, took much interest in the common penny; but to the imperial chamber, which limited the rights of the crown, he was so persistently hostile that it did no good in his day. An administrative council to which, after his defeat by the Swiss League in 1499, he was forced to agree, also failed in consequence of his opposition.

Foreign
war

The famous invasion of Italy by Charles VIII. of France in 1494 brought Maximilian into the field, and ever afterwards he mixed himself up in the confused struggles to the south of the Alps, hoping to assert the ancient claims of the German kings, at least in northern Italy. In 1508 he joined the infamous League of Cambray against the Venetian republic, and at a later time he took part in the conflict of the Holy League against Louis XII. of France. He was everywhere baffled, for his own territories, great as they were, did not suffice for his vast undertakings, and Germany refused to let herself be dragged into conflicts in which she was not directly concerned.

Period of the Reformation.

Decay of
feudal
relations.

The reign of Maximilian must be regarded as in many respects the end of the Middle Ages. The feudal relation between the king and the princes, and between the princes and their vassals, had become purely nominal. No real control was exerted by the crown over the heads of the various states, and now that war was carried on mainly by mercenary troops, the mediate nobles did not hold their lands on condition of military service. The princes were sovereigns, not merely feudal lords; and by the institution of local diets in their territories an approach was made to modern conceptions of government. The age of war was far indeed from being over, but men had at last begun to see that unnecessary bloodshed is an evil, and that the true outlet for the mass of human energies is not conflict but peaceful industry. By the growth of the cities in social if not in political importance the products of labour were being more and more widely diffused; and it was now incomparably easier than at any previous time for the nation to be moved by common ideas and impulses. The discovery of the New World, the invention of printing, the revival of learning, and many other causes had contributed to effect a radical change in the point of view from which the world was regarded; and the strongest of all mediæval relations, that of the nation to the church, was about to pass through the fiery trial of the Reformation. This vast movement, which began in the later years of Maximilian, definitely severed the mediæval from the modern world.

The
Reforma-
tion.

The seeds of the Reformation were laid at so remote a time as that of the conflict between the papacy and the empire. The arrogance and the ambition of the popes then stamped upon the minds of the people an impression that was never effaced. During the temporary struggle of Louis IV. with the popes of his day the old feeling revived with fresh intensity; all classes, clerical as well as lay, looked upon resistance to papal pretensions as a necessity imposed by the national honour. At the same time the spiritual teaching of the mystics awakened in many minds an

aspiration which the church, in its corrupt state, could ill satisfy, and which was in any case unfavourable to a merely external authority. The Hussite movement, shaking as it did many ancient beliefs and shattering many ancient institutions, further weakened the spell of the church. Still more powerful, because touching deeper elements of human nature and affecting a more important class, was the influence of the Renaissance, which, towards the end of the 15th century, passed from Italy to the universities of Germany. The men of the new learning did not sever themselves from Christianity, but they became indifferent to it, its conceptions seemed to them dim and faded, while there was a constantly increasing charm in literature, in philosophy, and in art. No kind of effort was made by the church to prepare for the storm which might have been foreseen. The spiritual princes, besides displaying all the faults of the secular princes, had special defects of their own, and as simony was universally practised, the lives of multitudes of the inferior clergy were a public scandal, while their services were cold and unimpressive. The moral sense was outraged by such a pope as Alexander VI.; and neither the military ambition of Julius II. nor the refined paganism of Leo X. could tend to revive the decaying faith in the spirituality of their office. Pope Leo by his incessant demands for money, and his unscrupulous methods of obtaining it, awakened bitter hostility in every class of the community.

The popular feeling for the first time found expression. Luther, when Luther, in 1517, nailed to a church door in Wittenburg the theses in which he contested the doctrine at the root of the detestable traffic carried on for the pope by Tetzel and his accomplices. In appearance a slight circumstance, this was in reality an event of vast significance; for it brought to the front, as the exponent of the national sentiment, one of the mightiest spirits whom Germany has produced,—a man who had certainly many faults, but who amply made up for them by the force of his intellect, the loftiness of his aims, and the rare combination of caution and audacity with which he devoted himself to noble causes. Under the influence of Luther's great personality the most active and progressive elements of the nation were soon in more or less open antagonism to the papacy.

When Maximilian died, the throne was computed for by his grandson Charles, by Henry VIII. of England, and by Francis I. of France. The first and the last were the only real candidates, and ultimately Charles was chosen. By the time he reached Germany in 1521, Luther had passed through his famous controversy with Eck; he had confronted the papal legate, Cajetan; he had burned the pope's bull. After this retreat was impossible; and his innumerable adherents waited with keen excitement to see on which side the new king would declare himself. Charles V. (1520–55), although a boy in years, was not really young. He soon made up his mind as to the general lines of his policy, and no one who knew his grave and obstinate spirit supposed that any influence would cause him to diverge from his path. He had no adequate conception of the strength of the feeling which had been aroused. He fancied, as had at first been imagined in Rome, that he had to deal with a monkish quarrel; at one time he even supposed that a little money would easily set the difficulty at rest. Nor did he ever comprehend the real nature of the questions which stirred the hearts of his subjects. For Charles, although a diplomatist of astonishing skill, was a man of cold and narrow nature; it was incredible to him that men should be genuinely moved by aspirations to which he was himself a stranger. Even if his knowledge had been far more exact, he would not have turned against the church. Since the interregnum none of the emperors, with the exception of Maximilian, had been powerful princes

521-82. apart from the empire, and some of them had been wretchedly poor and insignificant. Maximilian himself could not compete on equal terms with the leading European monarchs. Charles, however, was by far the most important sovereign of his time. He was king of Spain and the Two Sicilies, with the resources of the New World at his command, lord of the Low Countries and of the county of Burgundy, co-gegent with his brother Ferdinand of the great Austrian inheritance, and now he had been made king of Germany with a right to the imperial crown. To such a potentate it naturally seemed possible to restore the splendour of Charles the Great, and he early set before himself this ideal. But the protection of the church had always been looked upon as the chief function of the empire; he could not, therefore, desert it at the very time when it seemed to be in need of his services. He reserved to himself the same right as his predecessors to resist it in the realm of politics; in the realm of faith he considered that he owed it his entire allegiance. Moreover, he intended to complete the task at which his grandfather had worked in vain, the subjection of northern Italy; and in order to realize this scheme it was of high importance that he should in no way needlessly offend the pope. Hence, in 1521, in the diet of Worms, without really examining the positions of Luther, Charles issued an edict denouncing him and his followers, and placing him under the ban of the empire.

Alarmed lest the emperor's great power should be too freely applied in Germany, the electors had before his appointment exacted a promise that he would respect German liberties and institute the reforms which had been vainly demanded of Maximilian. At the diet of Worms steps were taken to give effect to these conditions. An administrative council was nominated for the government of Germany while Charles should be away; and the imperial chamber was so effectually re-established that, with the aulic council (which was at first subordinate to it, but ultimately became independent), it lasted till the destruction of the empire. A matricula was drawn up settling the number of troops to be raised for common purposes by each state; and this also was in force while the empire existed. Having made these arrangements, Charles invested his brother Ferdinand with the sole authority in the Austrian territories, and then left Germany, to begin soon after his long struggle with Francis I. of France.

While Charles was absent carrying on his wars with Francis, great disturbances took place in Germany. One of the most remarkable of Luther's friends was Ulrich von Hutten, a young noble, who, although penetrated by the enthusiasm of the Renaissance, was emphatically a man of action. His class, the nobles, had ever chafed against the supremacy of the princes; and it occurred to him that the Reformation might be made the means of effecting a total change in the constitution of the empire. As no general reform either in church or state could be effected while the nation was cut up into a large number of principalities, his plan was to combine against the princes all who were discontented with the existing order, and to place the emperor at the head of a united country. Then the nobles would obtain their due, peace would be secured throughout the land, and papal authority might be easily put down. The scheme was a great one, and Hutten inspired with his enthusiasm Francis von Sickingen, an energetic and popular Rhensish baron who could at any time attract a large army to his standard. A force of 12,000 men was soon collected, and the enterprise was begun in 1522 by an attack on the elector of Treves, who, being a spiritual prince, would not, it was supposed, receive the sympathy of the reforming party. For a moment it seemed as if this dream of a new empire might be realized; but it was too late to make so vast a change. Several princes united, and in 1523

Sickingen was defeated and slain, while Hutten, who had devoted pen and sword to his cause, died in loneliness and misery on an island in the Lake of Zurich.

This war was followed by another of a still more serious nature. The peasantry of Germany had grievances compared with which those of the nobles were imaginary, for they were treated as if they had no right to expect any ray of brightness in their dreary lot. Extravagant hopes were kindled among them by the Reformation, and in a few years, notwithstanding all Luther's efforts to dissuade them, widespread conspiracies were formed. In 1524 war broke out in the greater part of southern and central Germany, and the peasants, aided by a few valiant knights like Götz von Berlichingen, were at first triumphant. But they soon became so violent that Luther himself urged they should be sternly punished; and in 1525, after a vast amount of confusion and bloodshed, the rising was completely suppressed. By these two wars the authority of the princes was made greater than ever; the peasantry suffered if possible more severe oppression, and many even of the immediate nobles were compelled to submit to a yoke which they detested.

Notwithstanding the injurious impression caused by the struggles of the peasantry and of the barons, the Reformation made rapid progress, and those who remained loyal to the church became so alarmed that at the diet of Spire in 1526 they clamoured for repressive measures. The administrative council at the head of Germany in Charles's absence was, however, not unfriendly to the Reformers, and the diet ended by decreeing that, until the questions in dispute should be authoritatively settled, each state should have religious freedom. This proved to be a most important edict. As yet no religious body had been organized to compete with the Catholic Church; now the leading states in which the ideas of the Reformation prevailed began, under the guidance of Luther and Melancthon, to carry out measures which they had in vain hoped the church itself, by means of a general council, would undertake. The Catholics saw clearly the significance of what was done; and at another diet held in Spire in 1529 they obtained, in opposition to the previous edict, a new decree, forbidding further changes in religion. The supporters of Luther formally protested; but the Catholics maintained their ground. In the following year the emperor, who was no longer an untutored youth, but a sovereign famous for skill in council and success in war, came to Germany for the express purpose of making an end of heresy. At the diet he held in Augsburg the Lutherans submitted a sum-
mary of their doctrines in the Augsburg Confession, which had been drawn up, with the sanction of Luther, by Melancthon, and which was afterwards regarded as their chief standard of faith. Charles made no real effort to comprehend the controversy; he was resolved, whether the heretics had right on their side or not, that they should submit, and he had at first no doubt that he would awe them into submission by an unvonted display of power and splendour. To his surprise the Lutheran princes, while perfectly respectful, continued firm, and not only declined to attend mass, but had Lutheran services in their own quarters. Paying no attention to the edict of Spire of 1526, he renewed that which he had issued at Worms in 1521; and it seemed more than probable that if it were not obeyed he would soon have recourse to arms.

But fresh difficulties with France, and a threatened invasion of the Turks, who had besieged Vienna in 1529, forced him to mask his designs. In 1532 he granted the religious peace of Nuremberg, which conceded temporary toleration to the adherents of the Augsburg Confession, and this peace was repeatedly confirmed in the following years. Meanwhile, the Lutherans, both princes and cities, had increased their power by forming the League of Smalkald,

and this confederation ultimately took in, besides many cities of South Germany, most of the North-German cities and principalities. The Reformation in Germany was above all things a popular movement. It sprang directly from the heart of the nation, and, the conditions favourable to it being widely spread, it passed with extraordinary speed from one part of the country to another. Thus many princes, who would not of their own accord have deserted the church, were compelled to do so from political motives. They had been strong enough to undermine imperial authority, they were not strong enough to resist the pressure of the majority of their subjects.

His hands being full elsewhere, Charles was obliged to temporize during his second absence from Germany, and to send counsels of moderation to his brother Ferdinand, who had been elected king of the Romans. He never, however, gave up his original purpose. His plan was, when he should have leisure to devote himself to the task, to secure the meeting of a general council which should make all necessary reforms, and to insist, at whatever cost, on the Lutherans abiding by its decisions. The peace of Crespy, signed in 1544, gave him free scope; and he began by inducing Pope Paul III. to summon the council which ultimately met at Trent. At the same time he made vigorous preparations for war. He affected that he had no intention of fighting for religious objects, but merely wished to bring to subjection certain states which had set him at defiance. By those means he was able to detach from the League of Smalkald the reforming states which were without real enthusiasm, or which were too timid to enter upon a great struggle. Those which took up arms were so disunited that the troops sent to Charles from Italy and the Low Countries had no difficulty in joining him; and in 1546 he not only made himself master of the South-German Lutheran cities, but in the battle of Mühlberg completely routed the Saxons and took their elector, John Frederick, prisoner. Shortly afterwards the landgrave Philip of Hesse, who with the Saxon elector had been the main political support of Lutheranism, fell into his hands, and both were treated with great harshness. Charles took advantage of his triumph to issue what was called the "Interim," a confession which was to be obligatory on the Lutheran states until the council then sitting should conclude its labours. It was everywhere resisted, but most of the states had at least outwardly to submit. All Germany thus seemed to be at the emperor's feet. The Reformation had enabled him to deal both with the princes and the imperial cities as no sovereign had dealt with them for five centuries.

But his triumph was too great to be enduring. The Catholic princes themselves were alarmed at his predominance; King Ferdinand was alienated by his attempts to secure the crown for his son Philip; and the Lutheran princes chafed angrily under his severe rule. The general discontent found a representative in Maurice, a subtle and ambitious Saxon prince, who, caring little about doctrinal disputes but a great deal about the increase of his own importance, had sided with Charles against the Lutherans, and had been rewarded by being made John Frederick's successor. He now turned, under the influence of what motives it is hard to determine, and plotted against the emperor, forming an alliance with the chief Lutheran princes and with Henry II. of France, who eagerly caught the opportunity to profit by the dissensions in the empire. Charles heard vague rumours of what was going on; but he had been thrown off his guard by the ease with which he had hitherto attained his will, and carelessly trusted to chance. Suddenly, in 1552, Henry II. invaded Germany as protector of her liberties, and Charles learned that Maurice was marching rapidly to Innsbruck with the inten-

tion of making him prisoner. He fled, and all the advantages he had gained by the battle of Mühlberg were at once lost. Within six months he had to sign the treaty of Passau, agreeing that a diet should be summoned for the purpose of arriving at a new settlement, and that in the meantime Lutherans and Catholics should have like privileges. In 1555 the religious peace of Augsburg was concluded by the diet thus promised.

Henry II. had seized the bishoprics of Metz, Verdun, and Toul; and Charles endeavoured at the earliest possible opportunity to win them back. But his efforts failed; and thus in his last years the power he fancied he had thoroughly humbled began a series of depredations which were thenceforth to be continued at frequent intervals. Disgusted with his ill fortune, he handed over the government of Germany to his brother Ferdinand in 1555, having in the previous year entrusted Spain, the Two Sicilies, and the Low Countries to his son Philip.

The peace of Augsburg, instead of bringing tranquillity, was the cause of fresh discord. The toleration it conceded did not include the Calvinist or Reformed faith; only the Lutherans received liberty of worship. And even a Lutheran was not tolerated unless his prince chose to let him alone; for each secular state had the right to eject from its territory all who did not accept the doctrine it established. Thus Catholic, Lutheran, and Calvinist were exposed to irritating despotism; and each came to regard the other with hearty detestation. Another source of trouble was a clause in the treaty called the ecclesiastical reservation. It required that if a spiritual prince accepted the Augsburg Confession he should forthwith resign his lands. The Lutherans denied the validity of this clause; and notwithstanding the protests of the Catholics several prelates became Lutherans and kept their territories as secular possessions.

Ferdinand I. (1556-64), who, like all German sovereigns Ferdinand I. after him, was recognized as emperor without being crowned by the pope, had at one time been distinguished for his zeal for the church. But the experience of his brother had taught him the necessity of prudence; and he was also kept quiet by troubles in Bohemia and Hungary, both of which countries he had acquired by marriage, and to both of which the house of Hapsburg soon began to lay hereditary claim. He tried to moderate the excesses of each party, and was anxious that the council of Trent should follow a conciliatory policy. Maximilian II. (1550-76), one of the most Maximilian II. enlightened princes of his time, adopted the same line. He would have had the state withdraw altogether from religious disputes, and so sincerely did he carry out his principles that, although he was himself a Catholic, Protestant doctrines spread during his reign throughout the Austrian hereditary lands, from which they had hitherto been excluded. Rudolf II. (1576-1612) reversed the policy of his Rudolf II. immediate predecessors. The Jesuits, who had been hard at work, although without much success, during his father's reign, gained complete ascendancy over him; and acting on their advice he continually warred against the Protestants. But he was too weak to do much good to his friends or injury to his enemies. Trained in the gloomy court of Spain, he had come to be of a moody, variable temperament; and he was given to outbursts of violent passion, followed by abject submission to his advisers. So much confusion sprang from his incompetence that the archdukes of Austria, with the sanction of the Spanish branch of the house of Hapsburg, met in 1606, and placed the government of the hereditary lands in the hands of his brother Matthias. He took refuge among his Bohemian subjects, who, in 1609, wrung from him a royal charter, granting religious freedom to the nobles, knights, and cities, with the right to build churches on their own and the royal lands. Matthias, who succeeded him as emperor (1612-16), was almost as unfit

612-82. for the duties he assumed. He put forth his whole energy against Protestantism; but he could not in the least discourage it, and in his time it prevailed over by far the larger part of the Austrian territory.

Catholic reaction. By this time, however, there were signs of a great Catholic reaction which was to work fearful havoc in Germany. It was due mainly to the persistent zeal of the Jesuits. For a long time the Protestants absorbed the intellectual strength of the country; but many able scholars and divines among the Jesuits could hold their own with their antagonists, who afforded them excellent vantage ground by foolish and bitter controversies. These devoted missionaries of the church gave their attention mainly to the young, and during the reign of Rudolf they were fortunate enough to make a profound impression upon two princes, each of whom was destined to play a great part in the events of the time. These princes were Maximilian, duke of Bavaria, and Ferdinand, duke of Styria. The former early showed the fruit of his training by executing, in 1606, an unjust imperial mandate against the Protestant city of Donauwörth, and afterwards treating it as his own.

The Protestant princes, rendered suspicious by this arbitrary act, formed in 1608 a confederation called the Union, which was to last for ten years; and in response the Catholics, under the guidance of Maximilian, to whom they gave the command, united in a similar confederation called the League. As the Union was headed by the elector palatine, who was a Calvinist, many Lutherans, among them the Saxon elector, regarded it coldly. It acquired, however, immense importance by an alliance with Henry IV. of France, who, like Henry II., wished to profit by German quarrels. War was on the point of breaking out between the two confederations in regard to the Juliers-Cleves territory, but the Union did not venture to fight after the sudden death of the French king.

Ferdinand II. Ferdinand was even more vigorous than his friend in the defence of his religion. His faith was that of a genuine fanatic, narrow, intense, austere; and with the feelings of a monk rather than of a secular ruler, he began at once, on assuming the government of Styria, to extirpate Protestantism. Individuals and families were driven without mercy from their homes until at last a country which had been mainly Protestant became in appearance altogether Catholic. He was the heir of Matthias, and on coming to Vienna after the death of that sovereign, he found himself in the midst of what seemed hopeless confusion. The Bohemians, embittered by the violation of the royal charter granted by Rudolf, refused to acknowledge him as king, and elected Frederick V. of the palatinate, son-in-law of James I. of England; and the people of Hungary and of the Austrian lands, terrified by the prospect of a stern rule in opposition to their religious beliefs, were almost in open revolt. He succeeded in obtaining the imperial crown; and from that time Ferdinand II. (1619-37) was dominated by a fixed resolve to secure the triumph of his church throughout the empire,—a resolve which cost Germany the Thirty Years' War.

Thirty Years' War. He began with Bohemia. Although supported by Spain, he could not obtain from his sufficient troops for his purpose; and as he was for some time nearly powerless in Vienna he was obliged to come to terms with Duke Maximilian, who, after securing his own interests, put the army of the League commanded by Tilly at his disposal. The Union helped Frederick V.; but being a man of feeble character he wasted precious months, needlessly irritated his subjects, and vaguely hoped that his wife's father would see him out of his embarrassments. In 1620 his army was utterly routed at the battle of Weissenburg; and he and his family had just time to escape from the kingdom he had rashly undertaken to govern. Ferdinand drove to the

utmost the advantages of his victory. The Union was broken up; and Bohemia was placed under such a system of government that in becoming Catholic it lost more than two-thirds of its population, sank from high prosperity to a state of indigence, and ceased to be a seat of art and learning. The Spanish troops and the army of the League next invaded the palatinate, which after severe struggles, was Palatine finally subdued; and there also the process of conversion was carried on with a thoroughness which ended in the death or exile of multitudes of the inhabitants. Frederick was banished from his inheritance; and the electorate he was declared to have forfeited was conferred on Duke Maximilian.

Thus ended the first stage of the Thirty Years' War. The Danish second began (1625) by the formation, after much fruitless negotiation, of the Protestant League, which comprised England, Holland, and Denmark. The burden of the struggle fell on the last-named power, whose king, Christian IV., was also duke of Holstein, and therefore a prince of the empire. It was in the war with him that Europe first became familiar with the great name of Wallenstein, a Bohemian noble who, Wallenstein by marriage and by loyal service to the emperor, had risen to immense wealth and power. Ferdinand became restive at his dependence on the League, and gladly accepted Wallenstein's offer to raise an army over which it should have no control. This scheming, mysterious general, co-operating with Tilly and soon casting him into the shade, chased Christian, after the battle of Luttery, into Denmark, and overran Mecklenburg, of which he was created duke. He apparently intended to make himself master of the Hanse towns with the view of securing preponderance at sea as well as on land; but this purpose was thwarted by the bravery of the city of Stralsund, which he in vain tried to conquer. Denmark, however, was compelled to conclude peace in 1629.

Intoxicated by success, Ferdinand now issued the edict of restitution, demanding the restoration of all ecclesiastical lands of which the Protestants had become possessed since the treaty of Passau. As two archbishops and twelve bishops had become Protestant, this was to strike a tremendous blow at his enemies; and it stirred among them intense and universal opposition. At the same time, yielding to Duke Maximilian and other members of the League, he recalled Wallenstein, whose movements had given rise to suspicion. A more inauspicious moment could not have been chosen for those two important steps, for in 1630 Gustavus Adolphus left Sweden at the head of a well-disciplined army for the purpose of raising up the Protestant cause which had fallen so low. At first this great king was received coldly, even by his co-religionists. They were ignorant of his designs, and did not want a stranger to profit by the internal disputes of their country. A mistake at the outset would probably have proved fatal to him; but he saw the dangers of his position, and moved so warily that in less than a year he had obtained, partly by intimidation, partly by argument, the alliance of the duke of Pomerania and the elector of Saxony. Tilly, at the head of nearly the whole force of the League, met him at Breitenfeld, and was completely defeated. This victory put Germany at his feet; and had he realized how utterly he had broken the imperial strength, he might have advanced on Vienna itself. He preferred, however, to make the country around and behind him absolutely secure; and everywhere the cities opened their gates to him as the deliverer of the Protestants. After again defeating Tilly, who was wounded and died, he took possession of the palace at Munich, while Duke Maximilian fled. Whatever may have been the motives of Gustavus in undertaking this memorable expedition,—and they were probably not altogether unselfish,—he had the power of

kindling confidence and enthusiasm among those who depended upon him; and the result of his presence in South Germany was that the faith of the Protestants in their cause and in themselves revived, and that they no longer doubted of ultimate victory. The emperor felt how great had been his mistake in dismissing Wallenstein, and after many fruitless entreaties, at last persuaded him to come forth from his retirement and form a second army. He did so on condition that he should have absolute command; and so urgent was the need of his services that Ferdinand allowed him to make himself in this way a great and dangerous power within the state. In 1632 he was defeated at the battle of Lutzen; but the defeat was better than an ordinary victory, for the Swedish hero was among the slain. Wallenstein now aimed at becoming a great sovereign; perhaps he even aspired to the imperial crown itself. In any case his dilatory movements, his endless intrigues, and his haughty tone caused such profound uneasiness at Vienna that in 1634 he was got rid of by murder.

For fourteen years longer, although the original objects of the war were almost forgotten, the tempest continued to sweep over Germany. It received a fresh impetus from the intervention of Cardinal Richelieu, who, although the enemy of Protestants in France, thought fit to weaken Austria by aiding them in Germany. While Gustavus Adolphus lived, Richelieu was kept comparatively in the background; after the king's death he was one of the mainsprings of the war. At last, in 1648, after five years of negotiation at Osnabruck and Munster, the peace of Westphalia was concluded.

The Thirty Years' War settled once for all the principle that men should not be persecuted for their religious faith. It is true that the peace of Westphalia formally recognized only the three creeds, Catholicism, Lutheranism, and Calvinism, but so much suffering had been caused by the interference of the state with individual conviction, that toleration in the largest sense, so far as law was concerned, was virtually conceded. This was the sole advantage gained from the war by the Protestants. The Catholics insisted at first on keeping all the ecclesiastical lands which had been taken from them before the edict of restitution in 1630. The Protestants responded by demanding that they should lose nothing which they had held before 1618, when the war began. A compromise was at last effected by both parties agreeing to the date 1624,—an arrangement which secured to the Catholics their immense gains in Bohemia and the other territories of the house of Hapsburg. The restoration of the electoral palatine to part of his lands, and his reinstatement in the electoral office, were important concessions; but on the other hand, the duke of Bavaria kept the Rhenish palatinate, and, as he remained an elector, the votes of the Protestants in the electoral college were fewer by one than they had been in 1618.

The country suffered enormous territorial losses by the war. Up to this time the possession of Metz, Toul, and Verdun by France had never been officially recognized; now these bishoprics were formally conceded to her. She also received as much of Alsace as belonged to Austria. To the Swedes were granted Western Pomerania, with Stettin, and the bishoprics of Bremen and Verden. Those acquisitions, which surpassed the advantages Gustavus Adolphus had hoped to win, gave Sweden the command both of the Baltic and of the North Sea. In virtue of her German possessions Sweden became a member of the empire; but France obtained absolute control of her new territories. There was a further diminution of Germany by the recognition of the independence of Switzerland and the United Provinces. Both had long been virtually free; they now for the first time took the position of distinct nations.

In the political constitution of Germany the peace of Westphalia did not so much make changes as sanction those

already effected. The whole tendency of the Reformation 1632-41 had been to relax the bonds which united the various elements of the state to each other and to their head. It divided the nation into two bitterly hostile parties, and the emperor was not able to assume towards them a perfectly impartial position. His imperial crown imposed upon him the necessity of associating himself with the Catholics; so that the Protestants had a new and powerful reason for looking upon him with jealousy, and trying to diminish his authority. The Catholics, while maintaining their religion, were willing enough to co-operate with them for this object; and Germany often saw the strange spectacle of princes rallying round the emperor for the defence of the church, and at the same time striking deadly blows at his political influence. The diet was a scene of perpetual quarrelling between the two factions, and their differences made it impossible for the imperial chamber to move beyond the region of official routine. Thus before the Thirty Years' War the empire had virtually ceased to exist, Germany having become a loose confederation of principalities and free cities. For a moment the emperor Ferdinand appeared to have touched the ideal of Charles V., in so far, at least, as it related to Germany, but only for a moment. The stars in their courses fought against him, and at the time of his death he saw how far beyond his power were the forces with which even Charles had been unable to contend. The state of things which actually existed the peace of Westphalia made legal. So nearly complete was the independence of the states that each received the right to form alliances with any of the others or with foreign powers, nominally on condition that their alliances should not be injurious to the emperor or to the empire. Any authority which still lawfully belonged to the emperor was transferred to the diet. It alone had now the power of making laws, of concluding treaties in the name of Germany, and of declaring war and re-establishing peace. No one, however, expected that it would be of any real service. After 1654 it became a permanent body, and was attended only by the representatives of the princes and the cities; and from that time it occupied itself mainly with trifles, leaving the affairs of each state to be looked after by its own authorities, and those of the country generally to such fortunes as chance should determine.

It would not have been strange if so shadowy an empire had been brought altogether to an end. Some slight bond of connexion was, however, necessary for defence against the common dangers; and the empire had existed so long, and so many great associations were connected with it, that it seemed to all parties preferable to any other form of union. Moreover, Sweden, and other states which were now members of the empire, warmly supported it; and the house of Hapsburg, on which it reflected a certain splendour, would not willingly have let it die. An Austrian ruler, even when he spoke only in the name of Austria, derived authority from the fact that as emperor he represented many of the greatest memories of European history.

The effect of the Thirty Years' War on the national life was disastrous. It had not been carried on by disciplined armies, but by hordes of adventurers whose sole object was plunder. The cruelties they inflicted on their victims are almost beyond conception. Before the war the population was about twenty millions; after it the number was probably five or seven millions, and cannot have been more than ten. Whole towns and villages were laid in ashes, and vast districts turned into deserts. Churches and schools were closed by hundreds, and to such straits were the people often reduced that cannibalism is said to have been not uncommon. Industry and trade were so completely paralysed that in 1635 the Hanseatic League was virtually broken up, because the members, once so wealthy, could

which was more and more seen to be practically dead, but to the rivalry of two great German states, Austria and Prussia. The latter had long been laying the foundations of her power. Brandenburg, the centre of the Prussian kingdom, was, as we have seen, granted in the 15th century by the emperor Sigismund to Frederick, count of Hohen-zollern. In his hands, and in those of his prudent successors, it became one of the most flourishing of the North-German principalities. At the time of the Reformation Albert, a member of a subordinate branch of the house of Hohenzollern, happened to be grand master of the Teutonic Order. He became a Protestant; dissolved the order, and received in fief of the king of Poland the duchy of Prussia. In 1611 this duchy fell by inheritance to the elector of Brandenburg, and by the treaty of Wehlau, in 1657, in the time of Frederick William, the Great Elector, it was declared independent of Poland. By skill, foresight, and courage Frederick William managed to add largely to his territories; and in an age of degenerate sovereigns he was looked upon as an almost model ruler. His son, Frederick, aspired to royal dignity, and in 1701, having obtained the emperor's assent, was crowned king of Prussia. The extravagance of Frederick drained the resources of his state, but this was amply atoned for by the rigid economy of Frederick William I, who not only paid off the debts accumulated by his father, but amassed an enormous treasure. He so organized all branches of the public service that they were brought to a point of high efficiency, and his army was one of the largest, best appointed, and best trained in Europe. He died in 1740, and within six months, when Frederick II. was on the Prussian throne, Maria Theresa claimed, in virtue of the pragmatic sanction, the lands and hereditary titles of her father, Charles VI.

Frederick II., a young, ambitious, and energetic sovereign, longed not only to add to his dominions but to play a great part in European politics. His father had guaranteed the pragmatic sanction, but as the conditions on which the guarantee had been granted had not been fulfilled by Charles VI., Frederick did not feel bound by it, and revived some old claims of his family on certain Silesian duchies. Maria Theresa would not abate her rights, but before she could assert them Frederick had entered Silesia and made himself master of it. Meanwhile, the elector of Bavaria had come forward and disputed Maria Theresa's right to the succession, and the elector of Saxony had also put in a claim to the Austrian lands. Taking advantage of these disputes, France formed an alliance with the two electors and with the king of Prussia against Austria; and in the war which followed the allies were at first so successful that the elector of Bavaria, through the influence of France, was crowned emperor as Charles VII. (1742-45). Maria Theresa, a lady of a noble and undaunted spirit, appealed, with her infant son, afterwards Joseph II., in her arms, to the Hungarian diet, and the enthusiastic Magyars responded chivalrously to her call. To be more at freedom she concluded peace with Frederick, and ceded Silesia to him, although greatly against her will. Saxony also was pacified and retired from the struggle. After this Maria Theresa, supported by England, made way so rapidly and so triumphantly that Frederick became alarmed for his new possession; and in 1742 he once more proclaimed war against her, nominally in aid of the emperor, Charles VII. Ultimately, in 1748, she was able to conclude an honourable peace at Aix-la-Chapelle; but she had been forced, as before, to rid herself of Frederick by confirming him in the sovereignty of the territory he had seized.

After the death of Charles VII., Francis, grand duke of Tuscany, Maria Theresa's husband, was elected emperor. Francis I. (1745-65), an amiable nonentity, with the instincts of a shopkeeper, made no pretence of discharging

important imperial duties, and the task of ruling the hereditary possessions of the house of Hapsburg fell wholly to the empress-queen. She executed it with discretion and vigour, so that Austria in her hands was known to be one of the most formidable powers in the world. Her rival, Frederick II., was, if possible, still more active. The bitter experiences of his youth, although they had soured his temper, had not quenched the generous aspirations which had been fed by study of the best writers of his time. It did not occur to him, any more than to the other German sovereigns of the 18th century, to associate his people with him in the government of the country; he was in every respect a thoroughly absolute sovereign. Even his ministers performed but the duties of superior clerks. But he shared the highest ideas of the age respecting the responsibilities of a king, and throughout his long reign acted in the main faithfully as "the first servant of the state." The army he always kept in readiness for war; but he also encouraged peaceful arts, and diffused throughout his kingdom so much of his own alert and aggressive spirit that the Prussians became more intelligent and more wealthy than they had ever before been. He excited the admiration of the youth of Germany, and it was soon the fashion among the petty princes to imitate his methods of government. As a rule, they succeeded only in raising far larger armies than the taxpayers could afford to maintain.

Maria Theresa never gave up the hope of winning back Silesia, and, in order to secure this object, she laid aside the jealousies of her house, and offered to conclude an alliance with France. Frederick had excited the envy of surrounding sovereigns, and had embittered them against him by stinging sarcasms. Not only France, therefore, but Russia, Saxony, and ultimately Sweden, willingly came to terms with Austria, and the aim of their union was nothing short of the partition of Prussia. Frederick, gaining knowledge of the plot, turned to England, which had in the previous war helped Austria. At the close of 1755 his offer of an alliance was accepted to; and in the following year, hoping by vigorously taking the initiative to prevent his enemies from united action, he invaded Saxony, and began the Seven Years' War (1756-63).

The result of this war was to confirm Prussia for ever in the possession of Silesia, but it was followed by still greater indirect consequences. Prussia now took rank as one of the leading European powers, and by her rise a new element was introduced into the political life of Germany. Austria, although associated with the empire, could no longer feel sure of her predominance, and it was inevitable that the jealousies of the two states should lead to a final conflict for supremacy. Even before the Seven Years' War there were signs that the German people were tired of incessant imitation of France, for in literature they welcomed the early efforts of Klopstock, Wieland, and Lessing; but the movement received a powerful impulse from the great deeds of Frederick. The nation, as a whole, was proud of his heroic courage, his splendid military qualities, and his beneficent rule, and began, for the first time since the Thirty Years' War, to feel that it might, once more assume a commanding place in the world. This star of life ultimately revealed itself in the outburst of philosophic and literary activity represented by the names of Kant, Goethe, and Schiller. By that time Germany had not only asserted intellectual independence, but had become thoroughly tired of the national dissension and of the petty despotisms it imposed upon them.

In 1772 the necessities of Frederick's position compelled him to join Russia and Austria in the deplorable partition of Poland, whereby he gained West Prussia, exclusive of Danzig and Thorn, and Austria acquired West Silesia. After this he had to watch closely the movements of the

Joseph
II.

emperor Joseph II. (1765-90), who, although an ardent admirer of Frederick, was anxious to restore to Austria the greatness she had partially lost. The younger branch of the Wittelsbach line, which had hitherto possessed Bavaria, having died out in 1777, Joseph asserted claims to part of its territory. Frederick intervened, and although no battle was fought in the nominal war which followed, the emperor was obliged to content himself with a very unimportant concession. He made a second attempt in 1788, but Frederick again came forward. This time he formed a league for the defence of the imperial constitution, and it was joined by the majority of the small states. The memory of this league was almost blotted out by the tremendous events which soon absorbed the attention of Germany and the world, but it truly indicated the direction of the political forces which were then at work beneath the surface, and which long afterwards triumphed. The formation of the league was a distinct attempt on the part of Prussia to make herself the centre for the national aspirations both of northern and of southern Germany.

French
Revolution

The French Revolution was hailed by many of the best minds of Germany as the opening of a new era. Among the princes it excited horror and alarm, and in 1792 the emperor Leopold II. (1790-92), and Frederick William II., the unworthy successor of Frederick the Great, met at Pillnitz, and agreed to support by arms the cause of the French king. A more important resolution was never taken. It plunged Europe into a conflict which cost millions of lives, and which overthrew the entire state system of the Continent. Germany herself was the principal sufferer. The structure which the princes had so laboriously built up crumbled into ruins, and the mistakes of centuries were expiated in an agony of disaster and humiliation.

The states of the empire joined Austria and Prussia, and had there been hearty co-operation between the allies, they could scarcely have failed of success. While the war was in progress, in 1793, Prussia joined Russia in the second partition of Poland. Austria considered herself overreached, and began negotiations with Russia for the third and final partition, which was effected by the three powers in 1795. Prussia, irritated by the proceedings of her rival, did as little as possible in the war with France; and in 1796 she retired from the struggle, ceding to France her possessions on the left bank of the Rhine. The war was continued by Austria, but her power was so effectually shattered by blow after blow that in 1797 she was forced to conclude the peace of Campo Formio. Napoleon Bonaparte, to whose genius the triumph of France was mainly due, began separate negotiations with the states of the empire at Rastadt; but, before terms could be agreed upon, war again began in 1799, Austria acting on this occasion as the ally of England and Russia. She was beaten, and the peace of Lunéville added fresh humiliations to those imposed upon her by the previous war. France now obtained the whole of the left bank of the Rhine, the dispossessed princes being compensated by grants of secularized church lands and of mediæval imperial cities. The contempt of Napoleon for the empire was illustrated by his occupation of Hanover in 1803, and by his seizure of the duke of Enghien on imperial territory in 1804. In 1805 Austria once more appealed to arms in association with her former allies, but in vain. By the peace of Presburg she accepted more disastrous terms than ever, and for the moment it seemed as if she could not again hope to rise to her former splendour. In this war she was opposed not only by France, but by Bavaria, Württemberg, and Baden, all of which were liberally rewarded for their services, the rulers of the two former countries being proclaimed kings. The degradation of Germany was completed by the formation, in 1806, of the Confederation of the Rhine, which was composed of the

chief central and southern states. The welfare of the Rhenish empire was asserted to be its object, but a body of which Napoleon was the protector existed, of course, for no other purpose than to be a menace to Austria and Prussia. Francis II., who had succeeded Leopold II. in 1792, now resigned the imperial crown, and thus the empire and the German kingdom came to an end. The various states, which had for centuries been virtually independent, were during the next few years not connected even by a nominal bond.

End of
the Holy
Roman
empire

Frederick William III. (1797-1840) of Prussia, the successor of Frederick William II., had held selfishly aloof from the struggle of Austria with France. Alarmed by the Confederation of the Rhine, he suddenly resolved on war. Napoleon gladly accepted the challenge, and Prussia was so ill-prepared for the contest she had invited that the first serious battle—the battle of Jena—prostrated her at his feet. Aided by Russia, the king held out some time longer; but when, after the battle of Friedland, in 1807, the czar was detached from the alliance, Frederick William had to sign the treaty of Tilsit, by which he was deprived of the best part of his kingdom and of more than half his subjects.

In 1809 Austria made one more attempt to retrieve her fortunes, and at first not without success. After the battle of Wagram, however, Napoleon dictated peace from Vienna.

Germany was now thoroughly in the grip of France, and the French emperor proved how absolute was his power by annexing, in 1810, the whole northern coast as far as the Elbe. The completeness of the humiliation of Germany was the means of her deliverance. She had been taught self-respect by Frederick II., and by her great writers in literature and philosophy; it was felt to be intolerable that in politics she should do the bidding of a foreign master. Among a large section of the community patriotism became for the first time a consuming passion, and it was stimulated by the counsels of several manly teachers, among whom the first place belongs to Fichte. The Governments responded prudently to the national movement. Even in Austria timely concessions were made to her various populations. Prussia, under the guidance of her great minister Stein, reorganized her entire administration. She abolished serfdom, granted municipal rights to the cities, established an admirable system of elementary and secondary education, and invited all classes to compete for civil offices; and ample means were provided for the approaching struggle by drastic military reform. Napoleon had exacted an engagement that the Prussian army should be limited to 42,000 men. This was fulfilled in the letter, but in spirit set aside, for one body of men was trained after another until the larger part of the male population were in a position, when a fitting opportunity should occur, to take up arms for their country.

The disastrous retreat of the French from Moscow in 1812 delivered Germany the occasion she desired. In 1813 Prussia formed an alliance with Russia, which was ultimately joined by Austria, and in the great battle of Leipzig the issue was virtually settled. The first peace of Paris was soon followed by the escape of Napoleon from Elba; but in the battle of Waterloo he was decisively overcome, and Europe had no more to fear from his ambition. The Germans believed that by the second peace of Paris they ought to have received back all the lands which had ever been taken from them by France, but they had to content themselves with the recovery of their boundary as it had existed in 1792.

Between the conclusion of the first and the second peace Congresses of Paris the congress of Vienna had met and finished its labours. It was hard to reconcile the conflicting claims of so many states, and no party was fully satisfied with the compromise arrived at. The kingdom of Westphalia, and several other states set up by Napoleon, were brought to an

of
Germany

and. Prussia was compensated for her losses by receiving a part of Saxony, the Rhineland, and Swedish Pomerania; and to Austria were restored Salzburg, Vorarlberg, and Tyrol. Most of the members of the Rhenish Confederation were either left alone or deprived of small portions of territory; Hanover was made a kingdom, Weimar, Mecklenburg, and Oldenburg became grand duchies; and Lubek, Bremen, Hamburg, and Frankfurt were declared free cities.

German
confeder-
ation

In regard to the political constitution of Germany, the people were prepared for great and far-reaching changes. The need of union had been impressed upon them by the bitter experiences of nearly a generation, and they would have welcomed the establishment of a vigorous empire. But the jealousies of Austria and Prussia, and the hostility of the petty princes, prevented the popular policy from being adopted. Instead of an empire the congress formed the German bund or confederation. It was composed of 39 states, each of which was to be independent in regard to its internal affairs, the confederation taking cognizance only of matters of common interest. A permanent diet, in which each state should have its representative, was formed, it was to sit in Frankfurt, and to be presided over by the Austrian plenipotentiary. This body was to settle all disputed questions between the various states, each of which engaged never to make war on any of the others, nor to form alliances which should be injurious to a member of the bund.

Popular
lesire
or free
lom.

The events which arose from the French Revolution had awakened in the German mind not only a passionate desire for unity but an equally intense wish for freedom. Growing intelligence had revealed to the people that personal rule is ill-adapted to the wants of a civilized community, especially the personal rule of such men as the majority of their princes, who clung obstinately to every kind of abuse, and regarded their functions as a means rather of glorifying themselves than of promoting the general welfare. Humiliating as had been their submission to France, it had done something to deepen this conviction, for in the districts ruled by French officials a higher idea of human rights was introduced than had before prevailed, and what was great and attractive in the principles of the Revolution stirred general sympathy. So urgent were the demands for free government that, while the struggle with Napoleon remained undecided, the princes made lavish promises of concession after peace should be restored. The act of confederation contained a positive decree that in each state should be established a constitutional system.

Dual-
ity of
German
sovere-
igns.

The history of the next period is little more than a history of the elaborate and pitiful devices by which the German sovereigns evaded their engagements. Within a few years, indeed, the rulers of Nassau, Weimar, Bavaria, Baden, and Württemberg granted constitutions, but even in these countries absolutism was only in a slight degree modified. In Austria, where Prince Metternich was the controlling spirit, the most diverse nationalities were governed as if they had been a single people, and the methods of rule were as despotic and harsh as could be tolerated in a modern community. Although Frederick William III. of Prussia could not act upon quite so anti-quoted a system as Francis I., he resisted popular aspirations. The utmost concession he made was to appoint a number of provincial diets, which tended rather to foster than to allay the general discontent. Every opportunity was seized by the various Governments to repress the free movement of ideas. A number of students were guilty of some follies at a festival in the Wartburg, and some time afterwards a fanatical youth stabbed Kotzebue, the playwright, who had sided with the reactionary party. These incidents were held to be symptoms of a grave peril; and

in 1819 a conference of ministers at Carlsbad issued 1815-46 what were called the Carlsbad decrees, placing the univer- Carlsbad
sities under police supervision, reviving a rigid censorship, decrees.

A central commission of inquiry was also appointed for the purpose of hunting out secret societies, the very existence of which was merely subject of conjecture. In the diet, whose authority was slighted by these decrees, there were several members favourable to a consultative policy; and in the small states liberal politicians continued to demand parliamentary representation. The reactionists, however, were united and determined, and succeeded in thwarting political progress until 1830. Even in that year the Revolution Prussian and Austrian Governments were able to hold on in their old path, but the French Revolution caused so loud an outcry in countries in which the police were less powerful, that Hanover, Brunswick, Saxony, and Hesse-Cassel received constitutions, and in the lands where parliaments already existed the Governments granted freedom of the press, and promised more liberal legislation for the future. The two leading powers looked upon these changes with extreme disapproval, and they soon made use of the diet as a means of virtually annulling every measure that conflicted with their own aims. When the diet was instituted, it had been hoped that it would ultimately lead to closer national unity, and to the establishment of modern political institutions. It was now seen to be a mere instrument in the hands of the enemies both of unity and of liberty. So soon did the princes pluck up courage that in 1837 Ernest Augustus, who succeeded William IV. of England as king of Hanover, abolished the constitution which his predecessor had sanctioned, and set up another of an earlier period and of a far less liberal character. This unlawful act met with resistance which had to be put down by force. An appeal on behalf of the constitution was made to the diet, but with the result that was to be expected from its previous action, it declined to consider the question.

During this dismal period almost the sole political event to which Germans can look back with pleasure is the formation of the Zollverein or customs union. As in all other respects, the bund had failed to realize the expectations it had excited respecting the abolition of injurious restrictions on commerce. Several attempts had been made by groups of states to regulate their customs, but none of them had been attended with much success. At last Prussia arrived at an understanding with Bavaria, Württemberg, and several other states, and between 1833 and 1835 the union thus formed was joined by all German countries with the exception of Austria. It happened that about this time railways began to be introduced. The customs union enabled the nation to derive from them the utmost possible benefit, so that the prevalent political confusion did not hinder the population from attaining to considerable material prosperity. The obvious advantages of commercial union deepened the desire for unity in every great department of the national life, and at the same time raised the position of Prussia, which had been wise enough to associate itself with a most important movement.

It was not only by its relation to the customs union that Prussia attracted the attention and awakened the hopes of German liberals. In 1840 Frederick William IV. (1840-61) Frederick succeeded his father, and, as he was known to be a thoughtful and cultivated prince, there was a general expectation that he would abandon the arbitrary ideas of Frederick William III. He began his reign well. For some years the Government had been in conflict with the Catholic Church; the struggle was at once ended by graceful concessions. The king pardoned political prisoners, restored to their offices certain professors who had been degraded during the pre-

1840-48. vious reign for supposed revolutionary tendencies, and welcomed to the Berlin University the brothers Grimm, who, with five other professors, had been driven from Göttingen for protesting against the violence of Ernest Augustus. But it soon became manifest that Frederick William's favourite conception of "the Christian state" did not include any genuine exercise of political power by the nation, he wished to rule in a more enlightened spirit than his father, but not less absolutely. It was arranged that the provincial diets established by Frederick William III. should meet periodically, but this was a poor substitute for the great positive measures which had been anticipated. And within a very few years "the Christian state" was found to be compatible with a strict censorship, with the arbitrary punishment of schoolmasters, clergymen, and judges who did not meet the approval of the Government, and generally with incessant and irritating interference with the private life of the individual. The king lost all the popularity he had acquired in the early days of his reign by vaguely enthusiastic promises, and impartial observers saw that he and his people must sooner or later enter upon a serious struggle. A like state of things existed all over Germany. The German, Hungarian, Slavonic, and Italian subjects of the emperor Ferdinand (1835-48), who succeeded Francis I., were all agitating for reform; and in Bavaria, Hesse-Cassel, and Baden reactionary ministers were confronted by opponents who daily acquired increased influence among the masses of the population.

Prussian
united
diet.

In so many threatening forms did the rising spirit of the Prussian people reveal itself that in 1847 the king summoned to Berlin a united diet composed of the representatives of the provincial diets. This assembly truly expressed the popular feeling, but with so much moderation, and accompanying its demands by so many sincere assurances of loyalty, that it could not alarm the most timid. Frederick William, however, was offended by its tone, and haughtily proclaimed that he would never abate the rights which, as a lawful prince, he held by a higher than human authority.

Revolution of
1848.

Such was the condition of Germany at the breaking out of the French revolution of 1848. Its effect upon the public mind was immediate and profound. It had been made clear that no dependence was to be placed upon the engagements of the sovereigns, and that if anything was to be done it must be done by the people themselves. At a convention in Mannheim four demands were formulated—freedom of the press, trial by jury, national armies, and national representation. These demands were universally adopted as the liberal programme; and within a few days there was a liberal ministry in every one of the small states. In Bavaria, King Louis, whose well-meant efforts to make Munich a centre of art had not induced the nation to forget its political rights, resigned the crown to his son Maximilian. The popular excitement in Austria became so intense that Prince Metternich was dismissed, constitutional government was promised, and the Hungarians received a new cabinet. Still more vehement was the revolutionary movement in Prussia. Scenes of great violence occurred in the streets of Berlin, and on the 18th of March the king, who had previously tried to allay the storm by announcing that the united diet should meet periodically,—a concession he had refused to make at the proper moment,—declared that the national desire for a constitution should be satisfied. There was, however, a general feeling of distrust, and a conflict, which continued till the following morning, broke out between the troops and the population. Frederick William, who, although an ardent upholder of the divine right of kings, was too kind-hearted a man and too timid to approve of a struggle of this kind, laid aside his high pretensions, hanged his ministers, and asserted that he would place him-

self at the head of the national movement. By these means a more pacific temper was restored, and, after the united diet had passed an electoral law, the country was called upon to choose a national assembly.

It was not only reform in the individual states that was demanded in 1848; the majority of the people felt that the union time had come for sweeping away the effete bond which had done service only to the enemies of freedom, and for replacing it by a system of national representation which should maintain the dignity of Germany abroad and foster enlightened institutions at home. There was, indeed, a general conviction that only by means of a great central movement could the special agitations lead to enduring results. A number of deputies, belonging to different legislative assemblies, taking it upon themselves to give voice to the national demands, met at Heidelberg, and a committee appointed by them invited all Germans who then were, or who had formerly been, members of diets, as well as some other public men, to meet at Frankfurt for the purpose of considering the question of national reform.

About 500 representatives accepted the invitation. They constituted themselves a preliminary parliament, and at every time once began to provide for the election of a national assembly. It was decided that there should be a representative for every group of 50,000 inhabitants, and that the election should be by universal suffrage. A considerable party wished that the preliminary parliament should continue to act until the assembly should be formed, but this was overruled, the majority contenting themselves with the appointment of a committee of 50, whose duty it should be in the interval to guard the national interests. Some of those who were discontented with this decision retired from the preliminary parliament, and a few of them, of republican sympathies, called the population of Upper Baden to arms. The rising was put down by the troops of Baden, but it did considerable injury by awakening the fears of the more moderate portion of the community. Great hindrances were put in the way of the elections, but, as the Prussian and Austrian Governments were too much occupied with their immediate difficulties to resist to the uttermost, the assembly was at last chosen, and met at Frankfurt on the 18th May. The diet broke up, Frank- and the national representatives had before them a clear field. There is no reason to doubt that if they had acted with promptitude and discretion they would have succeeded in the task they had undertaken. Neither Austria nor Prussia was for some time in a position to thwart them, and the sovereigns of the smaller states were too much afraid of the revolutionary elements manifested on all sides to give way to reactionary impulses. But the Germans had had no experience of free political life. Nearly every deputy had his own theory of the course which ought to be pursued, and felt sure that the country would go to ruin if it were not adopted. Learned professors and talkative journalists insisted on delivering interminable speeches, and on examining in the light of ultimate philosophical principles every proposal laid before the assembly. Thus precious time was lost, violent antagonisms were called forth, the patience of the nation was exhausted, and the reactionary forces were able to gather strength for once more asserting themselves. The very first important question brought out the weaknesses of the deputies. This related to the nature of the central provisional executive. A committee appointed to discuss the matter suggested that there should be a directory of three members, appointed by the German Governments, subject to the approval of the assembly, and ruling by means of ministers responsible to the latter body. This elaborate scheme found favour with a large number of members, but others insisted that there should be a president or a central committee, appointed by the assembly,

while another party pleaded that the assembly itself should exercise executive as well as legislative functions. At last, after a vast amount of tedious and useless discussion, it was agreed that the assembly should appoint an imperial vicer who should carry on the government by means of a ministry selected by himself; and, by the decision of a large majority, the archduke John of Austria was chosen for the office. With as little delay as possible he formed an imperial cabinet, and there were hopes that, as his appointment was generally approved both by the sovereigns and the people, more rapid progress would be made with the great and complicated work in hand. Unfortunately, however, it was necessary to enter upon the discussion of the fundamental laws, a subject presenting many opportunities for the display of rhetoric and intellectual subtlety. It was soon obvious that beneath all varieties of individual opinion there were two bitterly hostile tendencies—those of the republicans, and those of the constitutionalists. These two parties attacked each other with constantly growing animosity, and in a few weeks sensible men outside the assembly gave up all hope of their dealing satisfactorily with the problem they had been appointed to solve.

In the midst of these disputes the attention of the nation was occupied by a question which had arisen before the outbreak of the revolutionary movements,—the so-called "Schleswig-Holstein question." In 1848 Christian VIII. of Denmark had officially proclaimed that Schleswig and the greater part of Holstein were indissolubly connected with the Danish monarchy. This excited vehement opposition among the Germans, on the ground that Holstein, although subject to the king of Denmark, was a member of the German confederation, and that in virtue of ancient treaties it could not be severed from Schleswig. In 1848 the German party in the duchies, headed by Prince Frederick of Augustenburg, rose against the Danish Government. Frederick VII., who had just succeeded Christian VIII., put down the rebellion, but Prussia, acting in the name of the confederation, despatched an army against the Danes, and drove them from Schleswig. The Danes, who were supported by Russia, responded by blockading the Baltic ports, which Germany, having no navy, was unable effectually to defend. By the mediation of England an armistice was concluded, and the Prussian troops evacuated the northern districts of Schleswig. As the Danes soon afterwards took possession of Schleswig again, the Prussians once more drove them back, but on the 26th of August an armistice of seven months was agreed upon at Malmö.

The new Frankfurt Government disapproved the conditions of this armistice; but, as it had empowered Prussia to act for it, it was obliged to accept what had been done. The majority of the assembly, furious at an arrangement which was denounced as a national humiliation, decided that the armistice should not be sanctioned. The ministry resigned; but, a new combination being impossible, it was replaced, and the assembly unwillingly agreed to accept the armistice, on the understanding that the Government should lose no time in negotiating for peace on fair terms. A large minority, however, was intensely dissatisfied. It was composed of the republicans and other radical sections; and when defeated, they appealed from the assembly to the people. The Government kept its place, but was unable to prevent a rising which led to the murder of two unpopular representatives. There were also temporary republican agitations in Baden and Württemberg.

While these events were in progress, it seemed not impossible that the Austrian empire would fall to pieces. Bohemia and the Italian states were in revolt, and the Hungarians strove with passionate earnestness for independ-

ence. Towards the end of 1848 Vienna was completely in the hands of the revolutionary party, and it was retaken only after desperate fighting. A reactionary ministry, headed by Prince Schwarzenberg, was then raised to power, and in order that a strong policy might be the more vigorously pushed forward, the emperor Ferdinand resigned, and was succeeded by his nephew, Francis Joseph.

The prospects of reform were not much more favourable in Prussia. The assembly summoned amid the revolutionary Prussian excitement of March met on the 22d May. Demands for a constitutional system were urged with great force, and they would probably have been granted but for the opposition due to the violence of politicians out of doors. The aristocratic class saw ruin before it if the smallest concession were made to popular wishes, and it soon recovered from the terror into which it had been plunged at the outbreak of the revolution. Extreme antagonism was excited by such proposals as that the king should no longer be said to wear his crown "by grace of God;" and the animosity between the liberal and the conservative sections was driven to the highest pitch when, in the midst of the struggle between the populace and the Government in Vienna, it was proposed that Prussia should support the cause of freedom. The motion, although at first rejected, was passed in a modified form. Before this, ministry after ministry had been appointed, but none had been so decidedly reactionary as to preclude the hope of a settlement. Now the king resolved to break finally with the liberals, and, notwithstanding a solemn warning addressed to him by a deputation from the assembly, he called to office a cabinet about whose intentions there could be no misunderstanding. On the pretext that fair deliberation was impossible in the capital, the assembly was ordered to meet in Brandenburg, troops were concentrated near Berlin, and a state of siege was proclaimed. In vain the assembly protested and continued its sittings, going even so far as to forbid the payment of taxes while it was subjected to illegal treatment. It was forced in the end to submit, but the discussions in Brandenburg were no more successful than those in Berlin. At last, on the 5th December, the king dissolved the assembly, granted a constitution about which it had not been consulted, and gave orders for the election of a representative chamber.

About the time that the Prussian parliament was thus Frank- created, and that the emperor Ferdinand resigned, the Frankfurt assembly succeeded in formulating the funda- mental laws, which were duly proclaimed to be the funda- mental laws of Germany as it was now to be constituted. The principal clauses of the constitution then began to be discussed. By far the most difficult question was the relation in which Austria should stand to the Germany of the future. There was a universal wish that the Austrian Germans should be included in the German state; on the other hand, it was felt that if all the various nationalities of Austria formed a united monarchy, and if this monarchy as a whole were included in the confederation, it would necessarily overshadow Germany, and expose her to unnecessary external dangers. It was therefore resolved that, although a German country might be under the same ruler as non-German lands, it could not be so joined to them as to form with them a single nation. Had the assembly adopted this resolution at once, instead of exhausting itself by pedantic disquisitions on the abstract principles of jurisprudence, it might have hoped to triumph; but Austria was not likely to submit to so severe a blow at the very time when she was strong enough to appoint a reactionary Government, and had nearly re-established her authority, not only in Vienna, but in Bohemia and in Italy. Prince Schwarzenberg took the earliest opportunity to declare that the empire could not assent to any weakening of its influ-

849-50. once. Bitter strife now broke out in the assembly. Two of the ministers resigned, and one of those who took their place, Herr von Gagern, proposed that, since Austria was to be a united state, she should not enter the confederation, but that her relations to Germany should be regulated by a special act of union. This of course meant that Prussia should be at the head of Germany, and recommended itself to the majority of the constitutional party. It was resisted by the Austrian members, who were supported by the ultramontanes and the democrats, both of whom disliked Prussia, the former because of her Protestantism, the latter because of her bureaucratic system. Herr von Gagern's proposal was, however, adopted. Immediately afterwards the question as to the character of the executive was raised. Some voted that a directory of princes should be appointed, others that there should be a president, eligible from the whole German nation, but the final decision was that the headship of the state should be offered by the assembly to some particular German prince, and that he should bear the title of emperor of the Germans.

¹opposed
impr. The whole subject was as eagerly discussed throughout the country as in Frankfurt. Austria firmly opposed the idea of a united German state, insisting that the Austrian emperor could not consent to be subordinate to any other prince. She was supported by Bavaria, but on the other side were Prussia, Brunswick, Baden, Nassau, Mecklenberg, and various other countries, besides the Hanseatic towns. For some time Austria offered no counter scheme, but she ultimately proposed that there should be a directory of seven princes, the chief place being held alternately by a Prussian and an Austrian imperial vicer. Nothing came of this suggestion, and in due time the assembly proceeded to the second reading of the constitution. It was revised in a democratic sense, but the imperial title was maintained, and a narrow majority decided that it should be hereditary. Frederick William IV. of Prussia was then chosen emperor.

town. All Germany awaited with anxiety the reply of Frederick William. It was thought not improbable that he would accept the honour offered him, for in the early part of his reign he had spoken of German unity as enthusiastically as of liberty, and, besides, the opportunity was surprisingly favourable. The larger number of the North-German states were at least not unwilling to submit to the arrangement; and Austria, whose opposition in ordinary circumstances would have been fatal, was paralysed by her struggle with Hungary. Frederick William had not, however, the courage of his opinions; the deputation which waited upon him was dismissed with the answer that he could not assume the imperial title without the full sanction of the princes and the free cities.

End of
Frank-
fort as-
sembly. This answer was in reality a deathblow to the hopes of German patriots, but the assembly affected to believe that its cause was not yet lost, and appointed a committee to see that the provisions of the constitution were carried out. A vigorous agitation began in the country for the acceptance of the constitution by the Governments. The king of Württemberg was forced to accede to it; and in Saxony, Baden, and Rhenish Bavaria armed multitudes kept the sovereigns in terror. Prussia, which, following the example of Austria, had recalled her representatives from Frankfurt, sent her troops to put down these risings, and on the 21st May 1849 the larger number of the deputies to the assembly voluntarily resigned their seats. A few republican members held on by it, and transferred the sittings to Stuttgart. Here they even elected an imperial Government, but they had no longer any real influence, and on the 18th June they were forcibly dispersed by the Württemberg military.

The
Julien. Although Frederick William had refused to become emperor, he was unwilling to miss altogether the opportunity

afforded by the difficulties of Austria. He invited the states to send representatives to Berlin to discuss the constitution of Germany, and he concluded a treaty with the kings of Saxony and Hanover. Two days afterwards the three allies agreed upon a constitution which was in many respects identical with that drawn up by the Frankfurt assembly. The functions of the executive were, however, extended, the electoral law was made less democratic, and it was decided that, instead of an emperor, there should be merely a supreme chief aided by a college of princes. This constitution was accepted by a number of states, which assumed the name of the "The Union," and on the 20th March 1850 a parliament consisting of two houses met in Erfurt. Both houses accepted the constitution; and, immediately after they broke up, the members of the Union assembled in Berlin, and a provisional college of princes was elected. By that time, however, the whole situation of Germany had changed. In the autumn of 1849 Austria had succeeded, by the help of Russia, in quelling the Hungarian insurrection, and she was then in no mood to let herself be thrust aside by Prussia. Encouraged by her, Hanover and Saxony had severed themselves from the Union, and Saxony, Württemberg, and Bavaria arrived at an understanding as to a wholly new constitution. Afterwards all four states, with several others, accepted the invitation of Austria to consider the propriety of re-establishing the Confederation. The representatives of the states favourable to this proposal came together in Frankfurt on the 4th September 1850, and acted as the restored diet.

Thus the issue to which the events of about a century had Austria been pointing was apparently raised; Germany was divided and into two hostile parties, one set of states grouping them-^{Prussia.} selves around Austria, another around Prussia. A difficulty Disturb-
which arose in Hesse-Cassel almost compelled the powers once in
to bring their differences to the test of war. In this small
state the liberal movement of 1848 had been followed by
reaction, and the elector ventured to replace Hassenpflug, the
unpopular minister who had been driven from power.
Hassenpflug, being detested by the chamber, dissolved it in
June 1850; but the new one was not less hostile, and
refused to sanction the collection of the taxes until it had
considered the budget. For this offence it also was dis-
solved, and orders were issued for the raising of the taxes
without its consent. Many officials refused to obey; the
judges remained loyal to the constitution; and when
attempts were made to solve the difficulty by the army, the
officers instructed to act resigned in a body. Meanwhile,
Hassenpflug had appealed to the representatives in Frank-
fort who claimed to be the restored diet, and under the
influence of Austria they resolved to support him. Prussia,
on the other hand, announced its determination to carry out
the principles of the Union, and to maintain the Hessian
constitution. Austrian and Bavarian troops having entered
Hesse, a Prussian army immediately occupied Cassel, and
war appeared to be imminent. Prussia, however, shrink-
ing from the conflict. Radowitz, the foreign minister, who had
so far pursued a vigorous policy, retired, and was replaced
by Mantuffel, who, although the whole Prussian army was
mobilized, began by making concessions. The Union was
dissolved; and after Austria had despatched an ultimatum
formulating her demands, the new minister met Prince
Schwarzenberg at Olmütz, and virtually yielded everything
he insisted upon. The difficulty in Hesse was to be left to
the decision of the German Governments; and as soon as
possible ministerial conferences were to be held in Dresden,
with a view to the settlement of the German constitution.

These conferences began in the last days of 1850. The Diet re-
Austrian Government strove to secure the appointment of
a stronger executive than had hitherto existed; but its pro-
posals met with steady opposition from Prussia. Every

Prussian scheme was in like manner resisted by Austria. Thus, from the sheer inability of the assembled ministers to devise a plan on which all could agree, Prussia and the states that had joined her in the Union were compelled to recognize the Frankfort diet. From the 12th June 1851 its sittings went on as if nothing had occurred since it was dispersed.

This wretched fiasco was hardly less satisfactory to the majority of Germans than the manner in which the national claims in Schleswig-Holstein were maintained. The armistice of Malmö having expired in March 1849, the war with Denmark was resumed. A considerable army was despatched against the Danes by the Frankfort Government, but on the 10th July an armistice was signed at Berlin for six months, and a year afterwards Prussia concluded peace. The inhabitants of the duchies, however, continued the war. During the interview at Olmütz between Count Manteuffel and Prince Schwarzenberg it was agreed that, like the affairs of Hesse-Cassel, those of Schleswig-Holstein should be submitted to the decision of all German states, but that, in the meantime, Prussia and Austria should act together. By the intervention of Austrian troops peace was restored; and when, early in 1852, the Government of Denmark, in providing a constitution for the whole monarchy, promised to appoint separate ministers for Schleswig and Holstein, and to do equal justice to the German and the Danish populations, the two powers declared themselves satisfied, and the Austrian forces were withdrawn. The diet also, after some delay, professed to be content with this arrangement. While it was discussing the subject, a conference of the European powers met in London, and settled that Frederick VII. of Denmark should be succeeded by Christian, duke of Glücksburg, and that the duchies should be indissolubly united to the Danish monarchy. Austria and Prussia accepted the protocol setting forth these results, but it was not signed by the diet.

In all these later events the first place had been taken by Austria. The temporary dissolution of the customs union in 1851 gave her an opportunity of trying to extend her influence; she demanded that a union should be formed of which she should be the leading member. A congress of all German states, with the exception of Prussia and one or two states which sympathized with her, was held in Vienna; and it was followed by several other congresses favourable to Austrian pretensions. Prussia, however, being here on strong ground, refused to give way; and not only was the customs union restored in accordance with her wishes, but Austria concluded with her in 1853 a treaty of commerce which embodied some important concessions.
